# PREFACE

In the three decades that have elapsed since the first edition of this book was published, the field of medical genetics has experienced explosive growth. The rate of change in the science and application of medical genetics that occurred in the period spanning the first through the fifth editions of this book has markedly accelerated. In the 1980s, genetics was viewed by most practitioners as an important but obscure corner of medicine. Now it is widely recognized that virtually all human disorders have a genetic component, and genetics is viewed as the key basic science in uncovering the mysteries of disease pathogenesis. The tools of molecular genetics have matured remarkably over these past three decades, to the point where the mutations that underlie most single-gene disorders are being reported week by week. This has resulted in insights into disease mechanisms that have solved medical puzzles that have existed for centuries. These advances are also providing new clinical approaches that vastly improve the ability to accurately diagnose these disorders, and in many instances offer new hope for treatment and prevention. Of even greater importance for the medical and public health communities, and the public, is the increasing ability to dissect the genetic contributions to common disorders. The relationships between nuclear and mitochondrial genotypes, epigenetics, environment and chance remain dauntingly complex, but powerful molecular and computational tools are now being applied to these problems. The promise of new approaches to prevention and treatment represents a new paradigm, which includes what some call “personalized medicine,” that will transform health care.

The sequencing of the human genome has captured public attention and raised both hopes and concerns. Clinical applications of genomics have expanded dramatically since the last edition of this book, most notably in cytogenomics and whole-exome or whole-genome sequencing. Nevertheless, it remains to be seen how quickly and to what extent the genetic approach will be incorporated into the day-to-day practice of medicine. The complexity of translating scientific developments

in genetics to clinical application is being increasingly recognized, particularly with respect to legal, ethical, psychological, economic, and social implications. The need to inform colleagues throughout medicine about advances in genetics and the principles of their clinical application has never been greater.

The continued excitement and progress in our field are reflected in further expansion of this book with several new chapters. The number of genetic disorders understood at the molecular level continues to increase and common disorders not traditionally viewed as “genetic” are included as genetic contributions are coming to light. The sheer mass of new information precludes continued publication of the complete chapters in hard copy. The print volume contains short summaries of each chapter along with a few illustrations and recent references of general relevance to the topic. The complete chapters are available on the PPMG6e website. Authors are expected to update the online version at least semiannually.

We continue to be grateful for the comments about previous editions provided by our colleagues. This edition is better for their input, and we accept full responsibility for the deficiencies that remain.

We warmly acknowledge, besides our contributing authors, the assistance of staff at Elsevier Health Sciences and our personal assistants, especially Sue Lief in Los Angeles. We appreciate the continued moral, scholarly, and spiritual support of Professor Alan EH Emery, one of the originators of this book.

Finally, just as this edition was being finalized, the other originator and senior editor of this book, David Rimoin, died after a brief illness. There have been many memorials and tributes to Dr Rimoin, and others will emerge in the future. This sixth edition of *Principles and Practice of Medical Genetics* is one such memorial, to which he made tremendous intellectual and organizational contributions.

# FOREWORD

In the previous five editions of *Principles and Practice of Medical Genetics*, our late colleague, Victor McKusick, masterfully reviewed the advances that had occurred during the years between the various editions. This sixth edition, which will be published 30 years after the first volumes in 1983, finds the practice of medical genetics in a new environment.

The search for and identification of disease genes have continued to be important in our understanding of genetic disorders. Such discoveries, first reported with the groundbreaking discovery in 1986 of the genes underlying chronic granulomatous disease and Duchenne muscular dystrophy, are now so frequently reported that they will not usually merit publication in a major journal.

Undoubtedly, sequencing of an individual's whole exome or genome is currently forcing dramatic changes in the way genetics is practiced on the clinical and research level. There will be not a single subfield of genetics that will not be profoundly reshaped in the coming years as a consequence of these new technologies. We already observe and welcome fundamental discoveries that revolutionize our understanding of human disease, evolution, and ancestry. Similarly, diagnosis, prognosis and therapeutics have been markedly improved. Even the relationship to our endobiome has to be rethought as a consequence of discoveries in the new field of metagenomics.

In practice, we now increasingly order sophisticated genetic tests to confirm a diagnosis with great accuracy that is already suspected clinically. For example, based on the careful study of the dystrophin gene, we are able not only to confirm a diagnosis but also to predict with considerable accuracy whether a young boy presenting with muscle disease is likely to have the more severe Duchenne muscular dystrophy, or the milder Becker phenotype. This ability to use widely available genetic testing in many clinical situations to dissect out clinical phenotypes with specific gene mutations is invaluable.

The most common genetic disease that we recognize, inherited or acquired, is cancer. Now genetic tests are ordered in families known or thought to be at risk for breast (and other) cancers. Treatment decisions are made for these patients who are found to carry mutant genes that confer increased risk for malignancy, and who might have already presented with cancer. Although we have a vastly greater understanding of tumor biology, as well as predictive laboratory tools, we still lack the ideal cancer treatment, as the tumor in each patient is unique. However, some genetic discoveries related to cancer treatment are among the first to define what many call "personalized medicine".

We are now increasingly using genetic technologies in a more preventive mode across a population, not just in a person in whom we are trying to confirm a diagnosis. The most frequent genetic testing done in the United States and the rest of the developed world in this fashion is that involved with newborn screening. We screen in the public health sector all 4.2 million babies born in the United States for more than 30 disorders, nearly of which are genetically determined. These tests are largely done with metabolite analysis using mass spectroscopy, but there are increasingly direct genetic analyses done as secondary tests. This genetic testing differs in that it is aimed at healthy babies, in an effort to identify and treat serious, often fatal genetic disorders before symptoms appear. The US Center for Disease Control and Prevention has recognized the expansion of newborn screening as one of the most important public health developments of the past 10 years.

The application of next generation sequencing to newborn screening is now in pilot studies and will ultimately be applied at all ages. The actual sequencing, which has been the most daunting issue, is rapidly becoming practical. The costs to sequence the whole exome or genome have dropped markedly, making it feasible to use these resources in an attempt to better understand the outcome of a known condition. For example, by looking across the whole genome of an infant who screens positive for sickle cell disease, it might be possible to identify phenotype-modifying loci and much better predict the course of this severe and variable condition.

Challenges to the broad use of next generation sequencing remain. These include the management of the flood of information that comes from such sequencing and filling gaps in phenotypic annotations of variations in a whole genome. It is likely that we will soon enter the time when information about the person's entire genome will be a part of the medical record and as such a part of medical practice. Such information will require the widespread adoption of the electronic medical record. With the genome sequence in one's medical record one can inquire about the genome over a lifetime, and annotations made to greatly enhance our understanding.

We currently lack the scientific, logistical, ethical and legal framework required for the appropriate and effective use of such information. We will most surely identify modifiers that affect disease states (some of which can possibly be clues to therapies), but we will have a wide array of findings, identifying disorders, which are late in onset and many that lack therapies or any other actionable outcomes. And, while the profession wrestles with issues about what to return of research results and incidental findings from next generation sequencing,

several companies have begun offering these genetic tests directly to the consumer.

Health professionals and the general public must have and will benefit from much expanded genetic education. Eventually, everyone will want to understand better their genetic makeup, their risks for disease, how to prevent serious consequences of disease predispositions, and the most appropriate treatments for overt disease. This sixth

edition of *Emery and Rimoin's Principles and Practice of Medical Genetics* is one effective mechanism for providing this education.

# PERSONAL MEMORIES OF DAVID RIMOIN

David and I first met in 1963 when we were both research fellows in Victor McKusick's Unit at Johns Hopkins Hospital. He studied dwarfism and I studied muscular dystrophies. He had an office opposite mine and we shared many experiences and events together until I graduated PhD in 1964 and returned to the UK. David was awarded his PhD a year or two later. We remained on close personal terms thereafter—including a wonderful stay at his home in Beverly Hills when I was Boeckmann Visiting Professor at UCLA. On another occasion we attended a meeting in Moscow (before perestroika and glasnost), which was very challenging for both of us. It was at this meeting when we conceived the notion of editing a new textbook on medical genetics.

Over the years, we worked closely together on *PPMG* and on several occasions he visited Edinburgh where I

was then working. In 2006, he was invited to give the annual *Emery Lecture* at Green College, Oxford University. He gave an excellent talk entitled "The skeletal dysplasias: clinical–molecular correlations" which was well-received by everyone.

I shall miss David greatly—his warmth, generosity and friendship. And of course his collaboration with the *Emery & Rimoin's Principles and Practice of Medical Genetics*.

## History of Medical Genetics

*Victor A McKusick\**Formerly University Professor of Medical Genetics, Johns Hopkins University, Physician,  
Johns Hopkins Hospital, Baltimore, MD, USA*Peter S Harper*

Institute of Medical Genetics, School of Medicine, Cardiff University, Heath Park, Cardiff, UK

This article is a revision of the previous edition article by Victor A McKusick, volume 1, pp 3–32, © 2007, Elsevier Ltd.

## 1.1 PREFACE (PETER HARPER)

Victor McKusick's chapter "History of Medical Genetics," which first appeared in the third edition of this textbook in 1996, has provided readers with a masterly account of the origins and development of the field, containing a remarkable amount of information in the limited space available. This has been a historical account as seen by somebody who has lived through most of it, and who has perhaps shaped the development of medical genetics more than any other individual. While this may at times have given a personal slant to the areas emphasized, it provides an unrivaled perspective on the field—indeed for many years it has been the only substantive account, no detailed history of medical genetics having appeared until recently (Harper, 2008).

McKusick's death in 2008 has sadly removed the possibility of him providing a revised edition of his chapter, but his continued active attention to, and involvement in, the detailed evolution of medical genetics, up to the very end of his life, seen particularly in his interest in the Human Genome Project (HGP) and in the updating of his catalog OMIM, not to mention his many unique photographs, means that the chapter is still of the greatest value, and that it would be wrong, as well as regrettable, were it to be discarded. At the same time though, the highly condensed nature of the text makes it difficult, if not impossible to edit without making radical changes.

Thus, for the present edition of this book, a compromise has been reached, whereby the chapter remains essentially intact, but is framed by this introduction and by a postscript outlining some of the relevant topics that the original chapter does not cover. The web-based format of this new edition will allow the chapter to

evolve progressively over the coming years, in keeping with changes in the field, which have not only seen continuing new advances, but have also shown the urgent need for the history of its recent past to be recorded and preserved.

## 1.2 INTRODUCTION

Medical genetics is the science of human biologic variation as it relates to health and disease. Clinical genetics is that part of medical genetics concerned with the health of individual humans and their families. Alternatively, clinical genetics can be defined as the science and practice of diagnosis, prevention, and management of genetic disorders.

Within recent years, medical genetics has become established as a clinical specialty, as the culmination of developments that began in 1956 with the description of the correct chromosome number of the human. With the discovery of specific microscopically visible chromosomal changes associated with clinical disorders, beginning with Down syndrome in January 1959, medical genetics acquired an anatomic base. Medical geneticists now had their specific organ—the genome—just as cardiologists had the heart and neurologists had the nervous system.

The anatomic base of medical genetics was greatly extended with the mapping of genes to chromosomes and specific chromosomal regions, at an ever-accelerating pace, during the past 30 years. Gene mapping has not only enlarged the base for medical genetics but, indeed, as pointed out to me by Charles Scriver (personal communication, 1980), has also provided a neo-Vesalian basis for all of medicine (1). Medical historians tell us that the anatomy of Vesalius published in 1543 was of pivotal importance in the development of modern medicine. It was the basis of the physiology of William Harvey (1628) and the morbid anatomy of Morgagni (1761). Similarly,

\*Deceased.

human gene mapping constitutes an approach to the study of abnormal gene function in all diseases; the gene mapping approach has been adopted by researchers in almost all branches of medicine in the study of their most puzzling disorders. Through mapping, they have sought the basic defect in these disorders, and their clinical colleagues have used mapping information for diagnosis and carrier detection. The ultimate anatomic basis for medical genetics, the DNA sequence, is provided by the HGP.

In this brief history of medical genetics, I trace the foundations of the field that were laid between 1865, when Mendel published his work, and 1956, when the correct chromosome number was reported. I then discuss the events of the past 50 years that have seen the main evolution of the discipline. Finally, I attempt some projections for the future.

### 1.3 FOUNDATIONS OF MEDICAL GENETICS BEFORE 1956

Medical genetics in many developed countries is now a recognized specialty. In the United States, for example, the American Board of Medical Genetics certifies practitioners in the field, including PhD medical geneticists; in 1991, the American Board of Medical Genetics became the 24th organization to join the family of certifying American specialty boards. Medical genetics is a rather unusual branch of clinical medicine; indeed, it may be nearly unique in that it originated out of a basic science. Most specialties started as crafts (or out of a technological advance such as radiography) and only subsequently acquired basic science foundations.

The basic science that developed before 1956 and served as the foundation for the developments of the past 50 years included Mendelism, cytogenetics, biochemical genetics, immunogenetics, and statistical, formal, and population genetics.

#### 1.3.1 Mendelism

The demonstration of the particulate nature of inheritance was the contribution of Gregor Mendel (1822–1884), a monk and later Abbot in an Augustinian monastery (Figure 1-1) in Brunn (now Brno), Moravia (now the Czech Republic). The terms dominant and recessive were his. The delay in recognition of his work has been attributed to various factors, but the most likely is poor timing; in 1865, when Mendel reported his findings and conclusions, the chromosomes had not yet been discovered. Because its physical basis, meiosis, had not yet been described, Mendelism had no plausible basis to qualify it over other possible mechanisms of inheritance such as blending inheritance, which was favored by Francis Galton (1822–1911) another of Mendel's contemporaries (151).

R. A. Fisher (1890–1962) (2) raised a question whether Mendel's results were “too good”; that is, the data agreed too closely with the conclusions (see the

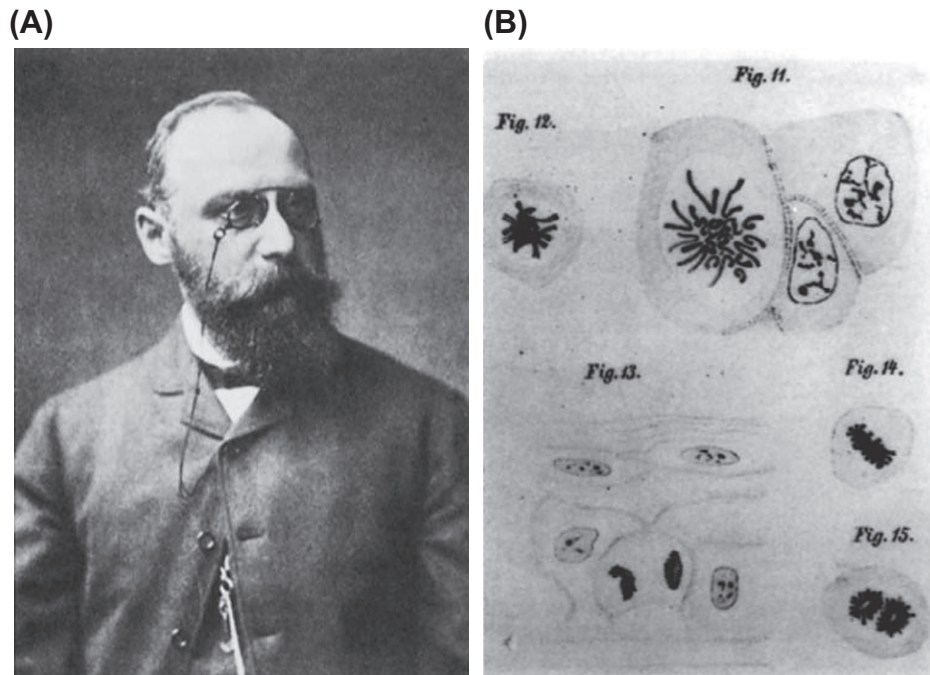

**FIGURE 1-1** (a) Mendel's monastery as it appeared in 1971. (b) Participants in the 2005 International Workshop on Genetics, Medicine and History, held at Mendel's Abbey, Brno.

discussion of this matter by Novitski (3)). (Mendel's “round” [R] versus “wrinkled” [r] trait in the garden pea has been shown to be due to a transposon insertion in the R gene for a starch-branching enzyme. The wrinkled state is due to lack of an osmotic effect present when the normally functioning enzyme is present. The first demonstration of mutation in the human due to insertion of a transposon was provided by the Kazazian group (4): a movable element from chromosome 22 was inserted into the factor VIII gene causing hemophilia A.)

Human chromosomes, visualized in tumor cells in mitosis, were pictured in a paper by Walther Flemming (Figure 1-2A), professor of anatomy in Kiel, in 1882 (Figure 1-2B). The term chromosome was introduced by Waldeyer in 1888. Mitosis and meiosis were described in the last quarter of the nineteenth century. (The term meiosis was introduced in 1905 by Farmer and Moore; the process had been previously referred to as the reduction divisions. The word meiosis, usually taken to mean “reduction in size of the pupil,” is from the same root. It is fortunate that the words are spelled differently in the two usages. In fact, Farmer and Moore spelled it “maiosis.” They wrote as follows: “We propose to apply

**FIGURE 1-2** A, Walther Flemming (1843–1905), discoverer of chromosomes (152). B, First illustration of human chromosomes, by Flemming (1882) (courtesy of the Genetics and Medicine Historical Network).

the terms Meiosis or Meiotic phase to cover the whole series of nuclear changes included in the two divisions that were designated as Heterotype and Homotype by Flemming.”)

During the 1880s, Roux, deVries, and Weismann developed the theory that the chromosomes carry determinants of heredity and development. The state of cytogenetics before the discovery of Mendel’s work was reviewed by E. B. Wilson (Figure 1-3) in his classic text (5). In a discussion of the Roux–deVries–Weismann theory (pp. 182–185), Wilson (5) wrote that “the chromatin is a congeries or colony of invisible self-propagating vital units ..., each of which has the power of determining the development of a particular quality. Weismann conceives these units ... [to be] associated in linear groups to form the ... chromosomes.”

In 1900, Mendelism was rediscovered independently by Hugo deVries (1848–1935) in Amsterdam, The Netherlands, Carl F. J. E. Correns (1864–1933) in Tübingen, Germany, and Erich von Tschermak (1871–1962) in Vienna, Austria. The chromosome theory of Mendelism was put forward about 1903 by Walter S. Sutton (1877–1916) (Figure 1-4), then a graduate student at Columbia under E. B. Wilson (6,7), and by Theodor Boveri (1862–1915) of Würzburg, Germany, a leading cytologist to whom Wilson dedicated his landmark book (1896). Sutton, a Kansas farm boy, had studied meiosis in the Kansas grasshopper at Kansas University under C. E. McClung. He was in New York in 1902 when William Bateson, the leading English champion for Mendelism, lectured there on the subject. Sutton promptly recognized the behavior of Mendel’s so-called factors in transmission from one generation to the next as exactly what

**FIGURE 1-3** E. B. Wilson (1856–1939), noted cytologist and author of *The Cell in Development and Inheritance* (1896).

one would expect if they were located on the chromosomes. The segregation of alleles and assortment of non-alleles were precisely what one would anticipate given the observed behavior of the chromosomes in meiosis.

William Bateson (1861–1926) had a difficult time converting biometricians to the Mendelian view of heredity.

**FIGURE 1-4** Walter S. Sutton (1877–1916), codeveloper of the chromosome theory of Mendelism.

These were the disciples of Francis Galton, including Karl Pearson (1856–1936), who favored blending inheritance. They were led to this view through experiences with the study of quantitative traits that we would call multifactorial. Their recalcitrance is evident in the following statement (8):

*As we have seen in the course of this work, albinism is a graded character, and we have every reason to believe that both in man and dogs separate grades are hereditary ... Mendelism is at present the mode—no other conception of heredity can even obtain a hearing. Yet one of the present writers at least believes that a reaction will shortly set in, and that the views of Galton will again come by their own.*

The views of the biometricians and Mendelists were reconciled by R. A. Fisher in a classic paper published in 1918 (9). Fisher showed that the Mendelian behavior of multiple genes functioning together can explain the findings of the biometricians in regard to quantitative traits. (In his 1918 paper, Fisher introduced the term “variance.”)

Bateson made many contributions to genetics, including the introduction of the term. In a letter written in 1905, related to a projected new professorship at Oxford

**FIGURE 1-5** Thomas Hunt Morgan (1866–1945), student of linkage and the first American-born Nobel laureate in medicine or physiology. Photo ca. 1910.

University (which he did not receive), Bateson wrote as follows:

*If the Quick Fund were used for the foundation of a Professorship relating to Heredity and Variation the best title would, I think, be “The Quick Professorship of the Study of Heredity.” No single word in common use quite gives this meaning. Such a word is badly wanted and if it were desirable to coin one “Genetics” might do. Either expression clearly includes Variation and the cognate phenomena.*

Another of Bateson’s accomplishments was the discovery (with Punnett) of linkage in the domestic fowl. They misinterpreted the phenomenon and assigned terms that have been perpetuated, however, coupling and repulsion signify whether the two mutant genes of particular interest are on the same chromosome or on opposite chromosomes, respectively. The true significance of linkage and the application of linkage and crossing over to chromosome mapping were contributions of Thomas Hunt Morgan et al. (1866–1945) working in the famous “fly room” at Columbia (Figure 1-5). Alfred Sturtevant was then a college undergraduate; Calvin Bridges and Hermann Muller were junior associates of Morgan. The unit of genetic map distance, the centimorgan (cM), was named for Morgan. He obtained his PhD in 1892 from Johns Hopkins University, he was the first native-born American to be awarded the Nobel prize in physiology or

**FIGURE 1-6** A, Exhibit by J. H. Tjio at the First World Congress of Human Genetics in Copenhagen (1956). Demonstration of  $2N=46$  in mitotic cells. B, Albert Levan in Lund, Sweden, in 1989. Collaborator of Tjio in work published in 1956.

medicine(1933),givenforhiscontributionstotheconceptof the gene.

In 1927, Hermann J. Muller (1890–1967) demonstrated that X-irradiation produces an increase in the rate of mutation in *Drosophila*. For this work, he received the Nobel prize in 1946.

### 1.3.2 Cytogenetics

During the 50 years after Flemming’s first picturing of human chromosomes in 1882, several attempts were made to determine the chromosome number in the human and to determine the human sex chromosome constitution. A particularly definitive paper appeared to be that of Painter (10), in which the diploid number of 48 was arrived at from study of meiotic chromosomes in testicular material from a hanged criminal in Texas. (There is probably no basis for the favorite suggestion of graduate students that the man may have had the XYY syndrome and therefore appeared to have 24, rather than 23, bivalents.) Painter commented that in some of his best preparations, the diploid number appeared to be 46. As an important contribution of the paper, Painter established the human XY sex chromosome mechanism.

In 1949, Murray Barr, working with Bertram in London, Ontario, discovered the sex chromatin, otherwise known as the Barr body, or X chromatin. The distinctive body was visualized in the nucleus of neural cells of the cat. A neuroanatomist, Barr, was studying changes in neural cells with repetitive stimulation of the nerves. Fortunately, he had sufficiently good records that he could establish that the unusual body in the interphase nuclei occurred only in female cats. Ten years later, when the XXY Klinefelter syndrome and the XO Turner syndrome, as well as other sex chromosome aneuploidies, were described, the correlation of the number of Barr bodies with the number of X chromosomes in excess of one was established. The correlation with X-inactivation and the Lyon hypothesis were likewise elaborated.

Twenty years after the paper of Barr and Bertram (1949, (11)), the fluorescent (F) body, or Y chromatin, was discovered in interphase nuclei by Caspersson et al. (12–14).

Three new techniques developed in the 1950s and early 1960s facilitated the burgeoning of human cytogenetics, including clinical cytogenetics. During the early 1950s, T. C. Hsu (sometimes known to his colleagues and friends as “tissue culture Hsu”) was working in Galveston when he accidentally discovered, through an error in the preparation of solutions, that hypotonicity causes nuclei to swell with dispersion of the mitotic chromosomes, improving visibility. In his paper, Hsu acknowledged that Hughes at Cambridge University had independently made the same discovery. This technical “trick” was used by J. H. Tjio and Albert Levan (15) (Figure 1.6 A and B) in studies of the chromosomes of fetal lung cells in mitosis and by Charles Ford (Figure 1.7A) and John Hamerton (Figure 1.7B) in studies of meiotic testicular cells (1956) to determine that the correct chromosome number of the human is  $2N=46$ .

In the early days of clinical cytogenetics, it was the practice to do bone marrow aspiration in order to get an adequate number of dividing cells for analysis. This requirement was avoided by the introduction of phytohemagglutinin by Peter Nowell (16–18). As its name implies, phytohemagglutinin is of plant origin and causes the agglutination of red cells. Its use was introduced by Edwin E. Osgood (1899–1970) of Portland, Oregon, for the purpose of separating white blood cells from red blood cells. It was Nowell’s observation that circulating lymphocytes exposed to phytohemagglutinin were stimulated to divide. Thus, it was possible to obtain from a sample of peripheral blood adequate numbers of dividing cells for chromosome studies.

The third technique of particular value to cytogenetics was the use of colchicine to arrest cell division in mitosis. Combined with phytohemagglutinin, it further helped ensure adequate numbers of cells at a stage of division optimal for chromosome identification and enumeration.

**FIGURE 1-7** Charles Ford (A) (at right) and John Hamerton (B) confirmed the  $2N=46$  in meiotic cells in 1956. Photographs taken in 1971 and 1974, respectively.

### 1.3.3 Biochemical Genetics

The acknowledged father of biochemical genetics is Archibald Garrod (1858–1936), who introduced the concept of inborn errors of metabolism, as well as the term (19). Alkaptonuria was the first of the disorders he investigated. In his paper on this condition in 1902, after coaching by Bateson, he recognized that its inheritance was probably Mendelian recessive because of the occurrence in both males and females with normal parents who were often consanguineous. In his famous Croonian lectures (delivered in 1908 and published in 1909), he formally unveiled the concept of inborn errors of metabolism and discussed three other conditions: pentosuria, albinism, and cystinuria. The nature of the enzymatic defect in all four of these disorders is now known. La Du et al. (20) confirmed Garrod's prediction of an enzyme deficiency in alkaptonuria by demonstrating deficiency of homogentisic acid oxidase in a liver sample. The gene mutant in alkaptonuria has been mapped to chromosome 3 by linkage studies; the gene encoding homogentisic acid oxidase has been cloned and a number of disease-causing mutations identified therein (OMIM 203500). The enzyme deficiency of tyrosinase in classic oculocutaneous albinism has been characterized all the way to the DNA level, and the enzymatic and genetic defects in other forms of albinism have been defined. On the basis of classic biochemistry, the enzyme defect in pentosuria is known to involve xylitol dehydrogenase (L-xylulose reductase); the gene has not been mapped. Cystinuria is not, strictly speaking, a Garrodian inborn error of metabolism but a defect in renal (and intestinal) transport of dibasic amino acids. It is caused by mutation in an amino acid transporter gene located on chromosome 2.

Bateson, Garrod's contemporary and advisor in matters genetical, is credited with the useful piece of advice: "Treasure your exceptions!" He was referring to findings

in experimental genetics and perhaps was emphasizing also the value of investigating rare mutants. The same message was conveyed by Archibald Garrod (21). He quoted a letter written by William Harvey a few months before his death in 1657:

*Nature is nowhere accustomed more openly to display her secret mysteries than in cases where she shows traces of her workings apart from the beaten path; nor is there any better way to advance the proper practice of medicine than to give our minds to the discovery of the usual law of nature by careful investigation of cases of rarer forms of disease. For it has been found, in almost all things, that what they contain of useful or applicable nature is hardly perceived unless we are deprived of them, or they become deranged in some way.*

Garrod was William Osler's immediate successor as Regius Professor of Medicine at Oxford University. He seems to have been sensitive to the prevailing view that the disorders he studied were unimportant because they were rare, especially in contrast to the infections and nutritional diseases rampant at that time. It was after his retirement from the Regius chair in 1927 that Garrod (22) wrote "The Inborn Factors in Disease, expanding his earlier Inborn Errors of Metabolism (23) to the full-blown theory of biochemical individuality." Indeed, as pointed out by Barton Childs (24), there was prophetic symbolism in the succession from Osler, who emphasized the disease that affected the patient, to Garrod, who focused on the patient affected by the disease.

Alkaptonuria was not the first inborn error of metabolism in which a specific enzyme deficiency was demonstrated. The first was hepatic glucose-6-phosphatase (G6P) deficiency demonstrated in glycogen storage

**FIGURE 1-8** Harry Harris (ca. 1974).

disease type 1 by Carl and Gerty Cori (25). (Diaphorase deficiency in methemoglobinemia was demonstrated by Gibson in 1948, but perhaps this cannot be considered a Garrodian inborn error of intermediary metabolism.) Deficiency of phenylalanine hydroxylase in phenylketonuria (PKU) was demonstrated soon after by Jervis (26). Asbjørn Følling in Norway had described PKU in 1934. The molecular nature of a mutation of the gene encoding phenylalanine hydroxylase (PAH; MIM 261600) in PKU was first described by Savio Woo et al. in 1986 (27).

Linus Pauling (1901–1994) introduced his concept of molecular disease during the late 1940s. It was an outgrowth of his focus on protein structure and specifically his work on sickle-cell anemia (with Itano) (28) demonstrating by electrophoresis that the hemoglobin molecule had an abnormal structure. By 1956, Vernon Ingram had narrowed the abnormality of the sickle hemoglobin molecule to a single peptide and by 1957 to a single amino acid difference.

By 1956 also, Oliver Smithies was writing about starch gel electrophoresis, opening up the study of human variation at the protein level. With this and similar methods, Harry Harris (1919–1994) at the Galton Laboratory extended the Garrodian concept of biochemical individuality (Figure 1-8).

As studies of the heredity of biochemical differences were going on, investigations of the chemistry of heredity were underway that would be the basis of what we now call molecular genetics. DNA had been discovered in fish sperm by Miescher in the nineteenth century. At the Rockefeller Institute for Medical Research in 1944, Avery et al. (29) demonstrated that the transforming factor, which changed the pneumococcus from a rough

form to a smooth form, is DNA. In 1953, Watson and Crick suggested a model for the structure of DNA consistent with its X-ray crystallography and with its biologic properties, including the capacity for replication.

### 1.3.4 Immunogenetics

Immunogenetics can be said to have had its start with the discovery of the ABO blood groups. These were demonstrated through the existence of “natural” antibodies (isoantibodies) by K. Landsteiner in 1901. From the distribution of ABO blood types in populations, Felix Bernstein in the early 1920s derived support for the multiple allele, one-locus explanation rather than the alternative two-locus (A, non-A and B, non-B) hypothesis. Yamamoto et al. (30) defined the molecular differences between the genes for blood groups O and A and between those for A and B.

The next-to-be-discovered blood group was MN, found by Landsteiner and Levine (31). These workers injected rabbits with different samples of human red cells and absorbed the resulting rabbit immune serum with other red cell samples until they found antibodies that distinguished human blood of the same ABO type.

Yet other blood group systems were discovered on the basis of antibodies (antisera) from mothers immunized to red cell antigens the fetus inherited from the father and antibodies from recipients of mismatched blood transfusions. The Rh blood group system is an example. As recounted by Race and Sanger (32), Levine and Stetson (33), in a brief but historic paper, described how the mother of a stillborn fetus suffered a severe hemolytic reaction to the transfusion of blood from her husband. The mother’s serum agglutinated the cells of her husband and those of 80 of 104 other ABO compatible donors. The antigen responsible was shown to be independent of the ABO, MN, and P groups. In 1940, Landsteiner and Weiner (34), having immunized rabbits and guinea pigs with the blood of the monkey *Macacus rhesus*, made the surprising discovery that the antibodies agglutinated not only the monkey red cells but also the red cells of about 85% of New York City white people, who were said to be Rh positive. Because the anti-Rh antibody was found in the blood of persons who had suffered reaction to the transfusion of ABO-matched blood, and the antibody of Levine and Stetson (33) was apparently identical to that raised in rabbits by injection of rhesus blood, the system was called rhesus (Rh). Levine et al. (35) showed that erythroblastosis fetalis is the result of Rh incompatibility between mother and child. Years later it became known that rabbit anti-rhesus and human anti-Rh antibodies are in fact not the same, but it was too late to change the name. Instead, the rabbit anti-rhesus antibody was called anti-LW, in honor of Landsteiner and Weiner. The LW antigen was later shown to be encoded by a gene on chromosome 19 that is quite distinct from the RH gene on chromosome 1.

Before 1956, blood groups provided some of the clearest examples of the role of Mendelism in the human, as well as some of the most important examples of the application of genetic principles in human health and disease, particularly blood transfusion and maternofetal Rh incompatibility.

### 1.3.5 Statistical, Formal, and Population Genetics

A cornerstone of population genetics is the Hardy-Weinberg principle, named for Godfrey Harold Hardy (1877–1947), distinguished mathematician of Cambridge University, and Wilhelm Weinberg (1862–1937), physician of Stuttgart, Germany, each publishing it independently in 1908. Hardy (36) was stimulated to write a short paper to explain why a dominant gene would not, with the passage of generations, become inevitably and progressively more frequent. He published the paper in the *American Journal of Science*, perhaps because he considered it a trivial contribution and would be embarrassed to publish it in a British journal.

R. A. Fisher, J. B. S. Haldane (1892–1964), and Sewall Wright (1889–1988) were the great triumvirate of population genetics. Sewall Wright is noted for the concept and term random genetic drift. J. B. S. Haldane (37) (Figure 1-9) made many contributions, including, with Julia Bell (38), the first attempt at quantitation of linkage of two human traits: color blindness and hemophilia. Fisher proposed a multilocus, closely linked hypothesis for Rh blood groups and worked on methods for correcting for the bias of ascertainment affecting segregation analysis of autosomal recessive traits.

**FIGURE 1-9** J. B. S. Haldane with Helen Spurway and Marcello Siniscalco at the Second World Congress of Human Genetics, Rome, 1961.

To test the recessive hypothesis for mode of inheritance in a given disorder in humans, the results of different types of matings must be observed as they are found, rather than being set up by design. In those families in which both parents are heterozygous carriers of a rare recessive trait, the presence of the recessive gene is often not recognizable unless a homozygote is included among the offspring. Thus, the ascertained families are a truncated sample of the whole. Furthermore, under the usual social circumstances, families with both parents heterozygous may be more likely to be ascertained if two, three, or four children are affected than they are if only one child is affected. Corrections for these so-called biases of ascertainment were devised by Weinberg (of the Hardy-Weinberg law), Bernstein (of ABO fame), and Fritz Lenz and Lancelot Hogben (whose names are combined in the Lenz-Hogben correction), as well as by Fisher, Norman Bailey, and Newton E. Morton. With the development of methods for identifying the presence of the recessive gene biochemically and ultimately by analysis of the DNA itself, such corrections became less often necessary.

Pre-1956 studies of genetic linkage in the human for the purpose of chromosome mapping are discussed later as part of a review of the history of that aspect of human genetics.

## 1.4 GROWTH AND DEVELOPMENT OF MEDICAL GENETICS: 1956 TO THE PRESENT

During the past 50 years, medical genetics has developed through a convergence of Mendelism, cytogenetics, biochemical genetics, immunogenetics, and statistical, formal, and population genetics. The development in each of these areas is traced in the preceding part of this chapter. Since 1956, medical genetics, in building on these foundations, has been blessed with three methodologies more or less specific to the field. These are “chromosomology” (beginning about 1956), somatic cell genetics (beginning about 1966), and molecular genetics (beginning about 1976). As will be indicated later, transgenic mice and all methods for transfer of genes into cultured cells or whole organisms, beginning about 1986, constitute a fourth methodological approach. The gene transfer methods, in combination with directed mutation and gene “knock-out,” have already proved particularly useful in the analysis of the function of genes, normal and abnormal.

Two further major methodological advances were database searching (research in silico or cybergenomics) as a primary method of genetic and genomic research and microarray technology for profiling of gene function. These began in the mid or late 1990s.

### 1.4.1 Chromosomology

Following the lead of Margery Shaw (personal communication, 1971), I divide the history of human cytogenetics into five ages (1) 1882–1956 (gestation), the period

**FIGURE 1-10** Discoverers of trisomy (a) Marthe Gautier (b) Jerome Lejeune (c) Raymond Turpin. 1984 (from Harper (2008), courtesy of Oxford University Press).

from the first publication on human chromosomes to the reports of the correct chromosome number; (2) 1956–1966 (a golden age of human clinical cytogenetics); (3) 1966–1969 (resting phase), a period when the field seemed to be “in the doldrums,” with little progress; (4) 1969–1977 (the banding era); and (5) 1977 to the present (the era of molecular cytogenetics).

Jerome Lejeune (1926–1994) and colleagues (Figure 1-10) opened up the field of clinical cytogenetics with their report in January 1959 of the extra small chromosome in mongoloid idiocy, as Down syndrome was then called. (A letter in *The Lancet* in 1961, containing a list of 19 signatories resembling a short Who’s Who in Human Genetics (39), established the eponymic designation as the preferred one. This is a prime example of the triumph of an eponym.)

The quinacrine fluorescence method was the first of the banding methods developed by Torbjørn Caspersson et al. (12–14) and exploited by Peter Pearson and others. This was followed by the various methods of Giemsa staining following alkali and other treatments for the so-called G-banding and by the method called reverse banding, or R-banding, because the Giemsa-light bands were stained.

The banding techniques permitted the unique identification of each human chromosome. This was immensely useful in experimental situations such as the study of rodent/human somatic cell hybrids (see Chapters 102, 103, and 139) and in the precise characterization of chromosomal aberrations. An early result was the demonstration that the smallest autosome is not number 22, but rather number 21, the autosome trisomic in Down syndrome. Jerome Lejeune had thought that Down syndrome is trisomy 21 of the next to the smallest autosome, not the smallest. Furthermore, it was demonstrated by Janet Rowley (40) (Figure 1-11) that the Philadelphia (Ph) chromosome involves the non-Down syndrome

**FIGURE 1-11** Janet Rowley at Bar Harbor Course, 1983.

chromosome, number 22, and that it represents a reciprocal translocation (with chromosome 9), not a deletion. The precise delineation of deletions and other aberrations permitted deletion mapping and mapping by dosage effects. An early, perhaps the first, example was the assignment of the locus for red cell acid phosphatase (MIM 171500) to 2p25 by Ferguson-Smith et al. (41). The refined cytogenetic delineation of aberrations in the chromosomes also permitted the recognition of “new” chromosomal syndromes. Because one could be reasonably certain of having a “pure culture” series of cases with the same anomaly, it was possible to establish karyotype–phenotype correlations. The trisomy 8 syndrome, the 5q– syndrome, the Pallister–Killian syndrome, and the Jacobson syndrome were examples.

By 1977, high-resolution cytogenetics involving the banding of extended chromosome in cells arrested in prophase or prometaphase had been introduced independently by Jorge Yunis (42), Uta Francke (43), and the Manilovs. This improved further the identification

of microdeletions in solid tumors such as Wilms' tumor and retinoblastoma, in 11p13 and 13q14, respectively. It revealed specific chromosomal abnormalities in congenital disorders of previously obscure etiology, including Langer–Giedion syndrome, Prader–Willi syndrome, DiGeorge syndrome, and Beckwith–Wiedemann syndrome. It provided the basis for the concept of contiguous gene syndromes put forward by Roy Schmickel (44).

The era of molecular cytogenetics, which persists to this day, began about 1977. With improved methods for studying DNA, the biochemical basis of banding was elucidated. The GC-rich nature of the Giemsa-light bands was demonstrated, and this information was correlated with evidence that these bands are also gene rich. Chromosomal *in situ* hybridization with radiolabeled DNA probes was first made to work reliably for single-copy genes in 1981, through the work of Mary Harper and Grady Saunders, Cynthia Morton, Malcolm A. Ferguson-Smith (Figure 1-12), and others. Because of high background noise and perhaps other factors, erroneous results had been previously obtained in experiments that attempted to map single-copy genes. Harper used dextran to create a “wad” of the isotopically labeled probe, thereby achieving a signal at the site of the particular gene that was well above the background level. In the initial paper by Harper et al. (45), the method was used to map the insulin gene to the tip of the short arm of chromosome 11. Fluorescent *in situ* hybridization, a non-isotopic method, was developed by Ward et al., Landegent et al., and others in about 1985.

The combination of molecular techniques with cytogenetic techniques permitted chromosome mapping of oncogenes and identification of their role in hematologic

malignancies associated with translocations. The MYC oncogene on chromosome 8 in Burkitt lymphoma was an early example elucidated by Carlo Croce, Philip Leder (Figure 1-13), and others; the ABL oncogene on 9q, involved in chronic myeloid leukemia, was worked out by Rowley, Heisterkamp, Grosveld (46), and others. Chromosome sorting with fluorescence-activated devices, followed by analysis of gene content by molecular genetic methods, was developed; for example, Lebo et al. (47) used this method specifically for gene mapping.

Deletions were also found in association with neoplasms, usually solid tumors. The classic example is retinoblastoma. Lionel Penrose et al. (48) were the first to find a deletion in any neoplasm, a deletion in chromosome 13 in retinoblastoma. (Deletions in retinoblastoma played a role in proof of the Knudson hypothesis (49) and in positional cloning of the RB1 gene.)

Chromosome microdissection, another method of physical mapping, was developed for collection of DNA from specific regions that could then be subjected to molecular genetic studies. For example, the approach was used by the Horsthemke group (50) to study the gene content of the region of 8q involved in Langer–Giedion syndrome, a contiguous gene syndrome (44).

## 1.4.2 Somatic Cell Genetics

A second large methodological advance in the era of human genetics since 1956 was somatic cell genetics. This has been contributory in several ways. In formal genetic analysis, it permitted the mapping of genes to specific human chromosomes or chromosome regions by the study of interspecies hybrids (e.g. between the human and the mouse). It permitted the differentiation of allelism and nonallelism disorders on the basis of noncomplementation or complementation, respectively, when cells from different patients with a given disorder (e.g. xeroderma pigmentosum) were mixed. In a third place, it permitted the study of the biochemical essence of many inborn errors of metabolism in cultured cells,

**FIGURE 1-12** Malcolm A. Ferguson-Smith with Marie G. Ferguson-Smith in Glasgow, 1981.

**FIGURE 1-13** Philip Leder at Bar Harbor Course, 1988.

usually skin fibroblasts. In a fourth and perhaps its most important application, somatic cell genetics provided an effective approach to the investigation of that vast category of somatic cell genetic disease—neoplasia.

Somatic cell genetics can be said to have gotten its start in the mid-1960s. The techniques that had been developed for culturing cells during the previous decades and the findings of studies of cultured cells were a useful background. No cell line has been subjected to more extensive study than has the HeLa cell. This cell line was isolated from the cervical carcinoma of a patient named Henrietta Lacks ([Figure 1-14](#)), who presented to the Johns Hopkins Hospital in early 1951 at the age of 31. Hers was one of some two dozen cervical carcinomas in which George O. Gey (1899–1970) attempted to establish a cell line and the only one yielding a successful result. The fact that it was an unusual cancer, indeed an adenosquamous carcinoma rather than the usual squamous cervical carcinoma, was found on review of the histology by Jones et al. ([51](#)). It had an unusual fungating appearance suggesting a venereal lesion and prompting a dark-field analysis for spirochetes (which were not found). Although there was no evidence of invasion or metastasis at the time she was first seen and despite radium therapy, Mrs Lacks was dead in 8 months. The genetic characteristics of the HeLa cell line, including HLA types, were determined by Susan Hsu et al. ([52](#)) and compared with the findings in surviving members of her family. That Mrs Lacks was a heterozygote for glucose-6-phosphate dehydrogenase (G6PD) deficiency (G6PD A/B) was established by the fact that she had both G6PD-deficient and G6PD-normal sons. The HeLa cell line is G6PD deficient (G6PD-A), indicating its monoclonal origin; this fact was established by Philip Fialkow ([53](#)) in studies of the monoclonality of cancers. The

vigor of the HeLa cell line is attested to by the extent to which it has contaminated other cell lines in laboratories around the world ([51](#)).

Based on the information acquired from studies of cultured cells, the HeLa cell being the prototypic human cell line, cell culture achieved wide use in studies of inborn errors of metabolism in the 1960s. Among the first of such studies, based on the wide enzymatic repertoire of the fibroblast, was that of galactosemia by Bias and Kalckar and by Robert Krooth in the late 1950s and early 1960s. Later in the 1960s, when Seegmiller with Rosenbloom and Kelley was defining the deficiency of hypoxanthine phosphoribosyl transferase (HPRT) in the Lesch–Nyhan syndrome ([54](#)), he would refer to making morning rounds on his tissue cultures. He alluded to the fact that cultured skin fibroblasts captured the essence of the patients' inborn errors of metabolism for study. Another notable example of the use of cultured cells in genetic studies was the Goldstein and Brown characterization, in the 1970s, of the low-density lipoprotein receptor and its role in normal cholesterol metabolism and familial hypercholesterolemia.

The development of prenatal diagnosis by amniocentesis was dependent on the fortunate circumstance that the amniocyte for the most part demonstrates the same enzymatic activities (or deficiencies) in cell culture as do other cells and tissues of the patient. Exceptions, however, include conditions such as type 1 glycogen storage disease (von Gierke disease) in which deficiency of G6P had been demonstrated by the Coris. Phenylketonuria proved to be another exception.

An important application of somatic cell genetics to formal genetics was the clonal proof of the Lyon hypothesis. Ronald Davidson, Harold Nitowsky, and Barton Childs ([55](#)) provided the most compelling evidence in the human. These investigators cloned two classes of cells from cultures of females heterozygous for the A/B electrophoretic variant of G6PD, one class of cells being type A and the other type B.

All cancer is genetic disease—somatic cell genetic disease. The chromosome theory of cancer was first clearly enunciated by Theodor Boveri in his monograph of 1914 (see [Reference 56](#) for biographic details).

Somatic cell genetics has played a big role in the proof and clarification of the genetic basis of cancer. It provided the methods by which the clonal nature of cancers was proved. Much of the molecular genetics of cancer such as the demonstration of oncogenes has been discovered through somatic cell genetics. The triad of methodologies that have been successively employed beginning in 1956—chromosomology, somatic cell genetics, and molecular genetics—have all played a role.

A particularly substantial contribution of somatic cell genetics has been to gene mapping (see later), specifically physical mapping, that is, the assignment of genes

**FIGURE 1-14** Henrietta Lacks, whose cervical carcinoma was the source of the clonal HeLa cell line.

**FIGURE 1-15** Guido Pontecorvo (right) with Dirk Bootsma at Third Human Gene Mapping Workshop, Baltimore, 1975.

to specific chromosomes and chromosomal regions, as opposed to genetic mapping, the determination of the interval between gene loci on the basis of amount of crossing over during meiosis. The method substituted interspecies (e.g. mouse and human) differences for interallelic differences used in meiosis-based linkage mapping. Somatic cell hybridization was what Haldane (Figure 1-9) called a substitute for sex and Pontecorvo (Figure 1-15) termed a parasexual method.

Somatic cell hybridization was made practical by the discovery of fusogens: first a virus, Sendai, by Y. Okada (57) and later a chemical, propylene glycol, by Guido Pontecorvo (58) (Figure 1-15). Both damage the plasma membrane of the cocultivated rodent and human cells, encouraging fusion. In the second place, the development of selection media allowed the isolation of hybrid cells from among the numerically overwhelming parental cells. The first of the selection media was hypoxanthine-aminopterin-thymidine (HAT), adapted to this use by John Littlefield (59) (Figure 1-16). The first human gene to be mapped by the method of somatic cell hybridization was that which encodes the cytosolic isozyme of thymidine kinase (TK1; MIM 188300). Mary Weiss and Howard Green (60), who mapped TK1 to a specific chromosome, recognized the power of somatic cell hybridization for chromosome mapping. Barbara Migeon and C. S. Miller (61) identified the TK1-bearing chromosome as belonging to group E, and after the advent of chromosome banding, Miller et al. (62) identified the chromosome as number 17. Through the work of Frank Ruddle (Figure 1-17), Walter Bodmer (Figure 1-18), and many

**FIGURE 1-16** John Littlefield at Bar Harbor Course, 1964.

**FIGURE 1-17** Frank Ruddle at Bar Harbor Course, 1987.

others, the application of somatic cell genetics to chromosome mapping was exploited to the fullest. During the 1970s, the somatic hybrid cell method accounted for the largest part of the progress in gene mapping that was collated in the regular Human Gene Mapping Workshops begun in 1973 (63).

**FIGURE 1-18** Walter Bodmer at Bar Harbor Course, 1979.

### 1.4.3 Molecular Genetics

The foundations of molecular genetics were laid in the pre-1956 era by the discovery of DNA, called nuclein, by Miescher in 1867; the demonstration that the pneumococcal transforming factor is DNA by Oswald Avery, Colin MacLeod, and Maclyn McCarty (1944); and the solution of the structure of DNA by Watson and Crick (64) (Figure 1-19). Working out the three-letter code of DNA was begun by Marshall Nirenberg and Heinrich Matthaei, who in 1961 observed the synthesis of a polypeptide composed solely of phenylalanine residues, when they used artificially synthesized RNA consisting only of uracil. Thereafter, the code was “cracked,” one trinucleotide at a time, with the complete Rosetta stone of molecular genetics becoming available by 1966.

Restriction enzymes that cut DNA at the site of specific sequences were discovered by Werner Arber and Hamilton O. Smith in about 1970, and Daniel Nathans showed that one can use the enzymes for mapping DNA, the so-called restriction map, first developed for SV40 viral DNA. The Southern blot method for displaying fragments of DNA created by dissection with restriction enzymes was developed by Edwin M. Southern in 1975 (65).

The discovery of specific restriction endonucleases made possible the isolation of discrete molecular fragments of naturally occurring DNA for the first time. This capability was fundamental to the development of molecular cloning (66), which opened up the era of recombinant DNA. The combination of molecular cloning and endonuclease restriction allowed the synthesis and isolation of any naturally occurring DNA that could be cloned into a useful vector and on the basis of flanking restriction sites, excised from it. The availability of a large variety

**FIGURE 1-19** Francis Crick (left) and James Watson at Cavendish Laboratory, University of Cambridge, 1953. (From *Photo Researchers*, with permission.)

of restriction enzymes significantly expanded the value of these methods.

The polymerase chain reaction (PCR) was a major addition to the molecular genetics armamentarium. PCR was formally unveiled in full technical detail by Mullis et al. (67) at the same historic *Cold Spring Harbor Symposium on Quantitative Biology*, Molecular Biology of *Homo sapiens* at which the HGP was discussed in a historic rump session. Combined with specific restriction enzyme cleavage at the mutation site, the method had been used in the diagnosis of sickle-cell anemia by Saiki et al. (68).

The first human gene to be cloned was chorionic somatomammotropin, by Shine et al. (69). About the same time, Tom Maniatis cloned two of the smallest human genes, those for the  $\alpha$ - and  $\beta$ -chains of hemoglobin. Most genes are at least 20 times bigger, and a few are as much as 1000 times bigger, containing much non-coding DNA (i.e. introns). After the discovery of reverse transcriptase, it was possible to take a shortcut and clone only the coding part of the gene complementary to the processed messenger RNA (mRNA), the so-called complementary DNA (cDNA). The cloning of large segments of DNA (up to a megabase or more) came in 1987 with the invention of YAC (yeast artificial chromosome) cloning by David Burke, Maynard Olson, and others (1987).

Two advanced methods for DNA sequencing were reported simultaneously in 1977, by Fred Sanger (70) and Maxam and Gilbert (71). Sanger and Gilbert shared the Nobel prize in chemistry in 1980. The Sanger dideoxy method for DNA sequencing remained the basic technology upon which the genetics revolution of the last vintage of the twentieth century was based, albeit major advances in automation and other modifications were made.

### 1.4.4 Chromosome Mapping

The first assignment of a specific gene to a specific human chromosome can be credited to E. B. Wilson (Figure 1-3), Columbia University professor and colleague of Thomas Hunt Morgan (Figure 1-5). Wilson (72) wrote as follows:

*In the case of color blindness, for example, all the facts seem to follow under this assumption if the male be digametic (as Guyer's observations show to be the case in man). For in fertilization this character will pass with the affected X chromosome from the male into the female, and from the female into half her offspring of both sexes. Color blindness, being a recessive character, should therefore appear in neither daughters nor granddaughters, but in half the grandsons, as seems to be actually the case.*

John Dalton (1766–1844), whose name is memorialized in the unit of molecular mass, had described his own color blindness in the 1790s; Swiss ophthalmologist Horner had described the pedigree patterns we now recognize as typical of X-linked recessive inheritance. (Even earlier, as indicated by Rushton in 1994 (73), Pliny Earle, a pioneer Philadelphia psychiatrist, in 1845 delineated the inheritance pattern of color blindness on the basis of his own family.) The sex chromosome constitution of the human had been assumed to be either XY or XO in the male and XX in the female, as a result of studies by Wilson's colleague N. M. Stevens.

In a famous paper in 1915, J. B. S. Haldane (1892–1964), with his sister Naomi and fellow student A. D. Sprunt, reported the first example of autosomal genetic linkage in a mammal. This was the linkage of “pink eye” (p) with albinism ©. The authors did not use the term linkage; the title of their paper was “Reduplication in mice.” It was published in the early stages of the “War of 1914” (World War I), and in the first paragraph the authors stated: “Owing to the war it has been necessary to publish prematurely, as unfortunately one of us (ADS) has already been killed in France.”

The first human genetic map interval to be estimated was that for color blindness and hemophilia. The transmission of hemophilia in the characteristic X-linked pedigree pattern was described in New England families early in the nineteenth century (74). J. B. S. Haldane with Julia Bell (38) in 1937 attempted an estimate of the interval on the basis of published pedigrees, and Haldane with C. A. B. Smith revised the estimate in 1947 (75). They placed the interval in the vicinity of 10cM; the fact that there are two forms of X-linked hemophilia (A, or classic hemophilia, and B, or Christmas disease) was not found until 1952, when in the Christmas issue of the *British Medical Journal*, Biggs et al. in Oxford, England, reported the case of a 5-year-old boy named Christmas with hemophilia of a distinctive type (76). It was distinguishable from classic hemophilia by the fact that serum from Master Christmas corrected the clotting defect in the blood of patients with classic hemophilia.

FIGURE 1-20 Lionel Penrose, 1973.

Subsequent studies of the linkage between hemophilia A and color blindness showed very tight linkage, and a reanalysis of the published hemophilia/cb data used originally by Haldane et al. led C. A. B. Smith to conclude that the series was a mixture of two forms of hemophilia, one very tightly linked to color blindness and one loosely linked or not linked at all. We now know that hemophilia B maps to the long arm of the X chromosome, but at a distance proximal to hemophilia A and color blindness, which are at the very tip of the long arm.

During the 1930s and 1940s, considerable thought was given to what approaches might be used to identify genetic linkage, recognizing that it is necessary in the human to use matings as they are found; one cannot, of course, create the matings that are most informative as one can in mouse and fruit fly. Lionel Penrose (1898–1972) (Figure 1-20) elaborated a sib-pair method in the 1930s (77). The first autosomal linkage in the human was not identified until the early 1950s, when Jan Mohr (Figure 1-21) demonstrated linkage of the Lutheran blood group and secretor factor loci as part of his doctoral thesis in the institute headed up by Tage Kemp (Figure 1-21) in Copenhagen. Mohr was subsequently the director of that institute, and it was in his department that the first-to-be-discovered autosomal linkage group (Lutheran and secretor) was determined to be located on chromosome 19 (78).

The method logarithm of the odds (lods) was developed by C. A. B. Smith in the 1950s and elaborated by Newton Morton. Using these methods, Morton (79) demonstrated linkage of the elliptocytosis and Rh blood group loci (including the demonstration of genetic heterogeneity, as some families did not show linkage). Renwick and others showed linkage of the ABO blood group to the nail–patella syndrome. All three of the early examples of autosomal linkage were established with blood groups (or, in the case of secretor factor, an “honorary” blood group), illustrating the pathetically limited repertoire of markers, a major handicap to gene mapping in that era.

**FIGURE 1-21** Jan Mohr (left) and Victor McKusick with plaque honoring Tage Kemp (1896–1964), Copenhagen, 1979. Mohr, Kemp's successor, was the director of the Institute of Human Genetics in Copenhagen. Kemp was the convener of the First World Congress of Human Genetics (1956).

By 1951, when the first autosomal linkage was discovered in the human, at least eight autosomal linkage groups had been identified in the mouse. On the other hand, it was about the same time in the early 1950s that the first X-linked locus was identified in the mouse, whereas three dozen or more loci were known to be on the human X chromosome because of X-linked pedigree patterns.

The first gene to be assigned to a specific autosome was the Duffy blood group locus, which was localized to chromosome 1 by Donahue et al. (80). At that time, R. P. Donahue was a candidate for the doctoral degree in human genetics at Johns Hopkins. As every graduate student in human genetics should probably do, he determined his own karyotype, although his thesis research was not on a cytogenetic problem. He identified a heteromorphism of the chromosome 1 pair. One chromosome 1 showed what looked like an uncoiled region (this was in the prebanding era) in the proximal portion of the long arm. Donahue had both the wit and the gumption to do a linkage study: the wit to sense that this might be a mendelizing character in his family, and the gumption to collect blood samples from widely scattered relatives, to determine marker traits, and to analyze the data. The analysis suggested linkage of the Duffy blood group locus to the “uncoiler” trait. Although the lod score was far below the value of 3.0 usually accepted as evidence for linkage, confirmation of the assignment came quickly from other workers.

After 1971, abundant information was collected on chromosome mapping by the method of somatic cell hybridization. Radiation by hybrid mapping made use of hybridization with rodent cells to “rescue” human cells in which random fragmentation of chromosomes had been produced by radiation. In situ hybridization of DNA probes to chromosomes, first with radioactively

**FIGURE 1-22** David Botstein at Bar Harbor Course, 1987.

**FIGURE 1-23** Ray White (left), James Neel (middle), and Joseph Nadeau at Bar Harbor, 1983.

labeled probes and later with fluorescent probes, was a mapping method first made to work reliably for single-copy genes in 1981.

About 1980, molecular genetics entered the chromosome mapping field. It contributed to the field in three ways: (1) it permitted direct identification of the human gene in somatic cell hybrids, so that it was possible to go directly for the gene, rather than requiring expression of the human gene in the hybrid cell; (2) it provided probes for chromosomal in situ hybridization, which was made to work for the first time in a reliable way for single-copy genes in 1981; and (3) it provided DNA polymorphisms as markers for family linkage study, thereby providing a virtually limitless repertoire.

In a seminal paper (81), David Botstein (Figure 1-22), Ray White (Figure 1-23), Michael Skolnick, and Ron Davis formally outlined the value of what they called restriction fragment length polymorphisms (RFLPs or “riflips”) as linkage markers in family studies. In fact, the first RFLP had been discovered by Kan and Dozy (82),

an HpaI variant 3' to the  $\beta$ -globin locus, and Ellen Solomon and Walter Bodmer (83) had suggested the value of such DNA variants as linkage markers:

*Given the range of available restriction enzymes, one can envisage finding enough markers to cover systematically the whole human genome. Thus, only 200 to 300 suitably selected probes might be needed to provide a genetic marker for, say, every 10% recombination. Such a set of genetic markers could revolutionise our ability to study the genetic determination of complex attributes and to follow the inheritance of traits.*

The late Allan C. Wilson (1934–1991) decried the use of the term restriction fragment length polymorphism, arguing that length mutations are one large class of mutations, the other being point mutations, and that it would be better to refer to these simply as restriction fragment polymorphisms. In mice they are referred to as restriction fragment length variants (RFLVs). Indeed this is what they are, differences between inbred strains and not polymorphisms in the strict sense as defined by E. B. Ford of Oxford University as the occurrence together in the same habitat of two or more distinct forms of a species in such proportions that the rarest of them cannot be maintained by recurrent mutation. Indeed, RFLPs in the human, when first discovered in a small number of samples, could not be known to be polymorphisms in the terms of this definition; 1% is usually taken as the minimal frequency of the rarer allele. However, it turns out that most DNA variants are indeed highly variable and qualify as polymorphisms within the Ford definition.

A second form of DNA variation to be discovered was variable number of tandem repeats (VNTRs), introduced as hypervariable DNA markers for linkage studies, as well as for use in forensic science by Jeffreys et al. (84) and by Nakamura et al. (85). The third major, and still more variable, type of DNA polymorphism is represented by the dinucleotide repeats, for example (CA)<sub>n</sub>, the so-called microsatellites. These were discovered and developed by James Weber at the Marshfield Clinic in Marshfield, Wisconsin, and by Michael Litt in Portland, Oregon; they are extensively exploited by many, particularly Jean Weissenbach in Paris, for the creation of genetic maps and the mapping of disease genes.

The first major successful application of RFLPs in linkage study was the mapping of the Huntington disease (HD) locus to the tip of chromosome 4 through linkage to the so-called GS8 RFLP; this marker at a locus designated D4S10 in the human gene mapping nomenclature was, in turn, mapped to that region of chromosome 4 by in situ hybridization. The initial demonstration of linkage was achieved by James Gusella et al. (86) on samples assembled by Nancy Wexler (Figure 1-24) from an extraordinarily large and extensively affected kindred with HD in the Lake Maracaibo region of Venezuela.

**FIGURE 1-24** Frank Ruddle (left) and Nancy Wexler at Bar Harbor, 1983.

**FIGURE 1-25** Haig Kazazian at Bar Harbor, 1976.

Haplotyping is the determination of markers close to, and on the same chromosome as, the mutation of interest. The term haplotype was first used in connection with the major histocompatibility types, HLA types. Haplotyping was developed particularly extensively by Haig Kazazian (Figure 1-25) and Stylianos Antonarakis (Figure 1-26) at Johns Hopkins University, in collaboration with Stuart Orkin in Boston and others, for identifying the presence of the gene for thalassemia in particular individuals. Because haplotypes represent closely linked markers, it is not unexpected that in families and even in population groups, common forms of thalassemia are associated with the same haplotype. This important application of the linkage principle in diagnosis and in population genetics (for tracing the multiple origins, e.g. of the sickle hemoglobin gene) was extended from the

**FIGURE 1-26** Stylianos Antonarakis at Bar Harbor, 1988.

hemoglobinopathies to many inborn errors of metabolism, particularly cystic fibrosis. Because of the many different mutations capable of causing cystic fibrosis and because of the relatively high frequency of the “cystic fibrosis” gene, tracing it in families through the haplotype has been useful.

In some populations, such as the Finns and the Old Order Amish, many usually rare disorders occur in relatively high frequency because of a founder effect. In such populations, most individuals affected with a recessive disorder that is rare in the general population are homozygous for a particular haplotype. Indeed, as was theorized by C. A. B. Smith in 1953 and elaborated more recently by Lander and Botstein (87) (Figure 1-27), patients with any rare autosomal recessive disorder, if the parents are consanguineous, will be expected to be homozygous for closely linked markers, that is, homozygous for a particular haplotype. This has indeed been shown to be the case in several disorders, including Bloom syndrome, diastrophic dysplasia, and alkaptonuria (88). Of course, in founder populations, a specific haplotype is likely to be shared in common by persons affected with an autosomal dominant or X-linked recessive as well.

Linkage analysis by the study of PCR-amplified DNA from individual sperm was introduced by Norman Arnheim in 1988 (89). Essentially, one could fill in the sort of information contained in stick diagrams used to explain linkage in textbooks of genetics. With this approach, it was not necessary to have observations on diploid offspring to identify recombinants among the gametes produced by the parent.

**FIGURE 1-27** Eric Lander at Bar Harbor, 1989.

Comparative mapping, most extensively pursued between mouse and humans, has been exploited as a clue to the likely location of genes in the human. A great deal of syntenic homology has been found between these two extensively studied species. The X chromosome in the human and in all other placental mammals has essentially the same genetic content, as was pointed out during the 1960s by Ohno (90), who also pointed out that the X chromosome is about the same size in all these organisms. The extensive syntenic homology, in the case of the autosomes, between the human and the mouse came as a surprise to many. What I have chosen to call the Oxford grid was developed by John H. Edwards, professor of genetics at Oxford University, and collaborators, particularly A. G. Searle, at nearby Harwell.

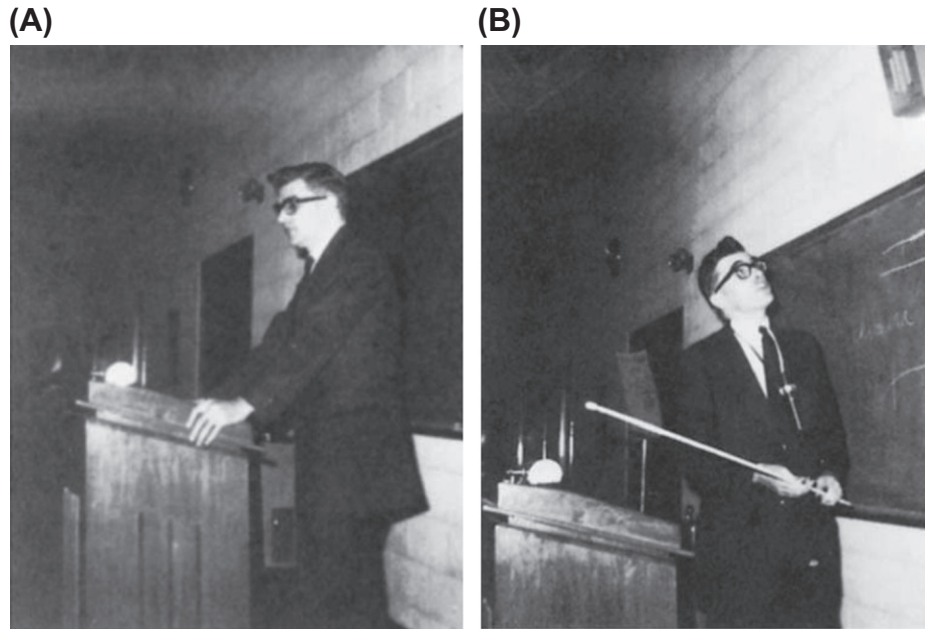

The term synteny, meaning “on the same chromosome,” was introduced by James H. Renwick (1926–1994) (Figure 1-28) in about 1970. It proved to be a useful term of distinction from linkage; two loci may be syntenic but not linked in the strict genetic sense because they are so far apart on the same chromosome that they assort independently through crossing over.

Renwick was also responsible for developing an early program for computer-assisted linkage analysis. Jurg Ott (91) also developed programs, as have others. These facilitated widespread analysis of linkage data.

A development of great importance for advancement of genetic mapping was the creation of the Centre d’Études du Polymorphisme Humain (CEPH) in Paris by Jean Dausset in 1983. CEPH created and maintains a reference panel of family DNAs for mapping by linkage. The three-generation family units consist of the four grandparents, two parents, and a minimum of eight children. The data on markers, as they are determined in these reference families in many laboratories, are collated, and new markers and genetic disorders can be mapped against the reference panel.

Radiation hybrid mapping was first devised by Goss and Harris (92) as a modification of mapping with

**FIGURE 1-28** A and B, James Renwick at Bar Harbor, 1972.

somatic cell hybrids. It involved fragmentation of the human chromosomes by irradiation of cultured cells and the “rescue” of these cells by fusion with mouse cells. The method was revived and revamped about 1990 by Peter Goodfellow of Cambridge University (93) and David Cox of Stanford University (94). Both created DNA panels from cells with various human chromosomal content.

The creation of clone libraries, for example, YACs, whose map location was known from radiation hybrid mapping or other methods made it possible to map a newly found sequence by hybridization or by linkage to a marker such as a sequence-tagged site (STS) or gene known to be on the same clone fragment. STSs were proposed by Maynard Olson et al. (95) as useful markers in mapping (96).

### 1.4.5 The HGP and Genomics

The goal of the HGP is to locate all the genes and sequence the entire haploid. It is primarily a mapping project; even sequencing was determined the ultimate map. In its initial form, however, it was not formally conceived as a mapping project. When proposed by Robert Sinsheimer, Walter Gilbert, Renato Dulbecco, and others in the period 1985–1986, the HGP was viewed as a project for complete sequencing of the genome. Previous progress in gene mapping and the value of the results were apparently unfamiliar to the leading promulgators, who were molecular geneticists. In part, objections to the project raised between 1985, when it was first proposed, and 1990, its official start date, resulted from the impression that it was an enterprise of mindless sequencing without much biology. (A factor also contributing to the unhappiness of many scientists with the project was

the price tag. The National Research Council/National Academy of Sciences (NRC/NAS) Committee on Mapping and Sequencing the Human Genome, commissioned in late 1986, and reporting out in February 1988, estimated that the “job” could be done in 15 years for \$200 million a year. Journalists in particular advertised the HGP as a \$3.0 billion project, which biologists coping with funding problems found disturbing. Of course, the annual budget of the National Institutes of Health (NIH) is approximately 50 times that figure (in 1988 dollars)!)

At a birth defects congress in The Hague in 1969, complete mapping of the genes on the human chromosomes had been proposed as an effective approach to solution of problems of congenital malformations and genetic disorders in general (97) (Figure 1-29). The proposal came close on the heels of the first manned Moon landing in July 1969; complete genome mapping was seen as the next Moon shot. The potential benefit of complete mapping was frequently emphasized thereafter. For example, it was advanced as an achievable goal for the last “vintade” of the twentieth century (98). Human Gene Mapping Workshops, initiated by Frank Ruddle in New Haven, Connecticut, in 1973, continued in the same form until 1991, for collation of the world’s experience in gene mapping. The function of these workshops was taken over by HUGO (see later).

It is true that the 1969 proposal had little apparent impact even though it was repeatedly restated over the next 15 years (1,98). In 1969, the methodology that would make the HGP possible was not yet at hand. As outlined elsewhere, recombinant DNA technology and methods of efficient DNA sequencing came in the 1970s; improved methods for both genetic and physical mapping

**FIGURE 1-29** Victor McKusick and the human gene map, Bar Harbor Course, 1981.

**FIGURE 1-30** At Howard Hughes Medical Institute-sponsored NIH conference on the proposed HGP, July 1986. Left to right: Victor McKusick, L. H. (Holly) Smith, James Watson, Walter Gilbert, Robert Sinsheimer.

came in the 1980s. As pointed out by R. Cook-Deegan ((99), p. 10) in his history of the HGP, whatever revisionist history might be written, the facts are that the HGP was conceived and promoted, not by medical geneticists, but by molecular biologists such as Robert Sinsheimer, Walter Gilbert (Figure 1-30), and Renato Dulbecco, who worked predominantly on organisms other than the human. And it was conceived and promoted apparently in ignorance, for the most part, of what had been accomplished and proposed in the area of gene mapping. It is true that in the 1986 Cold Spring Harbor Symposium devoted to the human genome, a long review was given of the status of the human gene map (100). This and the accompanying chromosome-by-chromosome lists of genes then mapped were an eye-opener to the molecular geneticists present. Also at that meeting, a rump session

**FIGURE 1-31** Francis Collins (left) with Leroy Hood, Cold Spring Harbor, 1993.

led by Gilbert and Paul Berg discussed the pros and cons of the proposed genome project (see Reference (99) for photographs of Gilbert, Berg, and Botstein at that crucial meeting and for a summary of the discussion).

If the period 1985–1990 was a gestational period for the HGP, the NRC/NAS committee (1988) was the midwife. The official birth date for the project in the United States was October 1, 1990, with federal funding jointly through the Department of Energy (DOE) (about one-third) and the NIH (about two-thirds). (The DOE through its national laboratories has long had a mandate to study the biologic effects of radiation. With the leadership of Charles DeLisi, then with the DOE, and the legislative initiative of Senator Pete Domenici of New Mexico, DOE became involved both intramurally (in its national laboratories) and extramurally in the HGP.)

James G. Watson (Figure 1-30) of Watson–Crick fame led the NIH program for its first 3 years, bringing to it both his prestige and his wisdom. At the same time he directed the newly created National Center for Human Genome Research (NCHGR), which functioned in much the same way as the individual institutes, he continued to direct the Cold Spring Harbor Laboratory on Long Island, New York. In 1993, Francis Collins (Figure 1-31) became the director of the NCHGR and proceeded to develop an intramural program in medical genetics. This reflects his conviction that the HGP is primarily a gene-finding enterprise and is linked to clinical medicine as both an efficient way to find genes and an effective way to realize potential benefits in diagnosis, prevention, and management of genetic disorders. The “center” became an institute, the National Human Genome Research Institute (NHGRI), on January 1, 1995.

In parallel with the HGP in the United States, genome programs were developing in many other countries, particularly the United Kingdom, France, and Japan. In September 1988, a group of 32 scientists from 14 countries met in Montreux, Switzerland, to found the Human Genome

**FIGURE 1-32** Founding council for the Human Genome Organization (HUGO) at Montreux, Switzerland, September 1988 (11 members were absent). First row (left to right): Matsubara, Shows, Tocchini-Valentini, Honjo, Shimizu, McKusick (with Swiss cowbell), Lyon, Gilbert, Cantor, Robson, Karpov (observer). Third row: Pearson, Dulbecco, Philipson, Jacob, Mirzabekov, Goodfellow (observer), Dausset, Watson, Worton, Southern, Grzeschik.

Organization (HUGO) (Figure 1-32). As a member of the organizing group, Norton Zinder, put it, “HUGO is a UN for the human genome.” It is a coordinating organization. Its founder president Victor McKusick was succeeded by Walter Bodmer in 1990, by Thomas Caskey in 1993, by Grant Sutherland in 1996, and thereafter by Gert-Jan van Ommen followed by Lap-Chee Tsui.

The HGP progressed even faster than predicted, mainly because of new methods: PCR (101), YACs (102), STSs (95), microsatellite linkage markers (103), and others. The official start date for the HGP in the United States was October 1, 1990. The completion date predicted by the 15-year estimate made by the NRC/NAS Committee on Mapping and Sequencing the Human Genome (104) was September 30, 2005. At the 5-year mark, Francis Collins (105) could report that the HGP was “ahead of schedule and under budget.”

A phenomenal speeding up occurred in the last part of the 1990s, with announcement of a “first draft” of the complete sequence in June 2000. The acceleration can be credited to the development of improved high-throughput sequencers that used capillaries for the dideoxy method developed by Sanger in 1977; and particularly to the application to the human of “shotgun” sequencing, which had been successful in the first complete sequencing of a free-living organism, *Haemophilus influenzae*, by the group of Hamilton Smith (106). Previously, the approach of the publicly funded HGP had been the creation of successive maps: a genetic linkage map of many genetic markers (103), a physical map of overlapping DNA segments (e.g. YACs; (102)), and finally the ultimate map, the DNA sequence. As opposed to this top-down approach, a bottom-up strategy, sequencing random fragments with assembly thereafter, was used by Venter et al. in the private genome project of Celera to get the complete genome sequence of microorganisms and subsequently of *Drosophila* (107) and the human.

The Human Mitochondrial Genome Project (HMGP), although never called that, had been completed long before. The HMGP had been done in an order opposite to the way the HGP was conducted. The complete sequencing was done first, by the group of Fred Sanger at Cambridge University (108). Then all the genes were identified, and finally disorders related to mutations in those genes were characterized.

The term genome appears to have been first used by Winkler in 1920 and to have been created by the elision of GENes and chromosOMEs to signify the set of chromosomes and the genes they contain (63). Thus, it is an irregular hybrid from two Greek roots. The term genomics is of more recent minting, having been proposed in July 1986 by Thomas H. Roderick of The Jackson Laboratory to designate the field of gene mapping and sequencing and specifically a new journal. The journal’s inaugural editorial (63) was entitled “A new discipline, a new name, a new journal.” The next 10 years showed a remarkable growth of the field and widespread use of the term genomics, so that in 1996 an editorial was entitled “An established discipline, a commonly used name, a mature journal” (109).

Goodfellow (1997) stated that he “would define genetics as the study of inheritance and genomics as the study of genomes.” Adjectives added to the word genomics have indicated specific aspects or applications of genomics. Mapping and sequencing constitute structural genomics. “Functional genomics,” continuing with Goodfellow’s definitions, “is the attachment of information about function to knowledge of DNA sequence.” Pharmacogenomics (110), toxicogenomics, comparative genomics, and physiologic genomics are some of the derivative terms for subfields of genomics (111).

Leading approaches for functional genomics are transgenic methods, which involve manipulation of the particular sequence in transgenic animals. Another

is database searching for similar sequences in other organisms where function is already known or can be determined more readily than is possible in the human. The latter is comparative genomics. Database searching has been referred to as research *in silico*, or cybergenomics.

Already before the HGP was completed, intense attention was directed to the function of the genome in a global sense as reflected by the protein gene products. Proteomics was a term invented about 1995 by Mark Russell who used two-dimensional display methods for peptides (112). Physiomics, a further derivation, is also called systems analysis or systems biology and refers further to function.

Functional genomics has also involved the study of gene expression as reflected by mRNA. Description of coordinated gene expression in various tissues, at various stages of development and in various physiological states, became possible with the development of micro-assay methods (chip technology) and other methods such as SAGE (serial analysis of gene expression) in the latter part of the 1990s. These methods for profiling gene expression represent the sixth of the major methodologies that have advanced medical genetics since 1956.

#### 1.4.6 Clinical Applications of Gene Mapping

Gene mapping, defined as the location of a gene to a specific chromosome site and/or the identification of markers that are close neighbors, has clinical value in diagnosis by the linkage principle and usefulness in identifying the nature of the basic defect either through positional cloning or through the candidate gene approach. J. B. S. Haldane (Figure 1-9) suggested in the 1920s that diagnosis by the linkage principle would be both possible and useful. In 1956, after Fuchs had suggested amniocentesis as a method of diagnosis of fetal sex based on the presence or absence of a Barr body in amniocytes, John H. Edwards (113) suggested that with amniocentesis one could do prenatal diagnosis by the linkage principle. The idea was further developed by McKusick (114), and McCurdy (115) demonstrated its practicability in connection with the hemophilia A carrier status, using the very closely linked G6PD marker. Schrott et al. applied the approach in connection with the closely linked myotonic dystrophy and secretor loci, the secretor status of the fetus being determinable in amniotic fluid (116,117). But the full strength of the linkage approach was not realized until the 1980s, when abundant DNA markers became available. As indicated earlier, haplotypes (i.e. clustered markers around the disease locus) were useful in the thalassemias and in some inborn errors of metabolism. Usually, however, linkage is an arduous, and not always practicable, approach because it requires the availability

of multiple family members and heterozygosity of the marker traits in key individuals. Furthermore, even under ideal circumstances, the available markers may be a distance from the disease locus, creating the possibility of a small, but finite chance of recombination, yielding false results. Thus, it is preferable to go for DNA diagnosis, that is, diagnosis based on the precise gene lesion.

In those disorders in which an enzyme deficiency or other protein abnormality has been identified, the wild-type gene can be cloned and defects in the gene identified. In the case of many Mendelian disorders, however, the nature of the biochemical defect was a mystery until the introduction of the mapping approach to identify the basic derangement. The first of the mystery diseases to be mapped by linkage to DNA markers was HD (86). It was, however, almost exactly 10 years to the week before the nature of the gene defect was reported (118).

Map-based gene discovery involves positional cloning and the candidate gene approach. Positional cloning was referred to initially as reverse genetics (119). Starting with the phenotype, mapping it and then going to the gene is, however, the approach of classic genetics; true reverse genetics will be increasingly practiced as fragments of DNA with transcriptional and other characteristics of a gene are investigated to determine their role in the phenotype, by methods such as transgenic, or “knockout,” mice. For this reason, Francis Collins (120) (Figure 1-31) suggested that the approach be called positional cloning, not reverse genetics (119,121). Table 1-1 lists, in chronological order of discovery, the disease-producing genes identified by positional cloning (that is, “walking in” on the gene from flanking markers) up to January 1994.

Whereas positional cloning and the candidate gene approach are map-based cloning, functional cloning starts with the functional gene product and uses reverse transcriptase to create a cDNA corresponding to the mRNA encoded by the particular gene. The candidate gene approach involves mapping the disease phenotype to a particular chromosomal location and then scrutinizing that chromosomal region for genes encoding enzymes or other proteins that might plausibly be implicated in the disease in question. Support for the involvement of the candidate gene in the disease is provided by the demonstration of absolute linkage of a RFLP or microsatellite marker within the gene with the disease in question, and the proof is clinched by the demonstration of a specific point mutation or other intragenic lesion. Elucidation of the defect in one form of hypertrophic cardiomyopathy by Seidman et al. (122,123) is an early example.

Many methods for identification of intragenic lesions have been identified over the past 10 years. By late 1994, disease-producing point mutations had been identified in almost 350 genes, and in many of these (e.g. CFTR, HBB) they numbered in the hundreds.

**TABLE 1-1 Map-Based Gene Discovery: Positional Cloning (Selected Examples)<sup>a</sup>**

Disorder	Gene	Location	MIM No.	Year
Chronic granulomatous disease, X-linked	CYBB	Xp21.1	306400	1986
Duchenne muscular dystrophy	DMD	Xp21.2	310200	1986

<sup>a</sup>In addition to these Mendelian disorders, many genes with somatic mutations involved in neoplasia have also been identified by positional cloning, starting, for example, from translocation breakpoints.

MIM, *Mendelian Inheritance in Man* (144).

## 1.4.7 Evolution of Clinical Genetics

Knut Faber (124) attributed to Mendel a major role in shaping our thinking about nosology, particularly the classification of disease and the delineation of distinct disease entities. The advent of the bacteriologic era in the decades immediately after Mendel also had a powerful effect on nosology. Both developments sharpened the focus on etiology: the role of specific microorganisms or the role of specific mutant genes. Until little more than a century ago, jaundice, dropsy, anemia, and other disorders were treated like disease entities in medical textbooks and in medical thinking and practice. Although Mendelian thinking contributed importantly to the general concepts in medicine, genetics did not become involved significantly in clinical medicine until after the acquisition of an anatomic base, beginning in the late 1950s.

One can point to several examples of pre-Mendelian “pedigree genetics.” Patterns characteristic of autosomal dominant and autosomal recessive inheritance were commented on by Maupertuis in the 1750s, by Adams in

1814 (125), and by Sedgwick in the 1860s. The X-linked recessive pattern of hemophilia was noted in a newspaper account in the 1790s and in medical reports by Otto in 1803 and Hay in 1813 of early New England families (74, 126). Similarly, the X-linked recessive pedigree pattern of color blindness was described clearly by Swiss ophthalmologist Horner in Zurich in 1876 and even earlier by Earle (127) in Philadelphia.

The relationship of consanguinity to an increased frequency of genetic defects was demonstrated by Bemiss in 1857 in studies of congenital deafness.

Early post-Mendelian examples of pedigree genetics include a report of albinism as a recessive by William E. Castle at Harvard in 1902. Farabee, a graduate student with Castle, described brachydactyly as a Mendelian dominant trait, basing his thesis research on a family in his home town of Old Concord, Pennsylvania. The family was subsequently updated by Haws and McKusick (128). Harvey Cushing, the neurosurgeon and biographer of William Osler, published a large kindred with symphalangism (his term for ankylosis of the phalanges)

in a paper with accompanying foldout pedigree in the first issue of *Genetics* in 1916, which also contained the famous paper by Calvin Bridges on nondisjunction.

The three main principles of clinical genetics (perhaps they should be called the three main phenomena of significance to clinical genetics) are pleiotropism, genetic heterogeneity, and variability. The history of our understanding of each can be traced.

Pleiotropism refers to multiple phenotypic (i.e. clinical) effects of a single mutant gene. This phenomenon is important to clinical medicine because often an external feature that is part of the pleiotropism and that may be in itself benign and insignificant may point to the presence of serious internal disease and/or to the fact that the person is a carrier of the mutant gene. The term was introduced by Plate in 1910. Hadorn developed the concept in considerable detail on the basis of studies in *Drosophila*. In his *Animal Genetics and Medicine* (129), Hans Grüneberg gave numerous examples, particularly from the mouse, and presented what he called “pedigrees of causes” relating all features of the syndrome back to a unitary defect. Analysis of pleiotropism, with the demonstration of plausible pedigrees of causes, was an important aspect of heritable disorders of connective tissue (130). The evidence for a unitary basic defect was fundamental to research in Marfan syndrome and other disorders. It took more than 35 years for the prediction of a unitary connective tissue defect in Marfan syndrome to be substantiated and particularized (131,132).

Genetic heterogeneity means that any one of several genetic mechanisms can lead to the same or similar phenotype. The idea was implicit in the work of Johannsen of Copenhagen, who in the first decade of this century distinguished phenotype and genotype. It was he who introduced the two terms (as well as the word “gene”) and put forward the concept that the phenotype is no necessary indication of the genotype. Genetic heterogeneity is obviously of practical importance in clinical medicine, as the prognosis, appropriate genetic counseling, and effective treatment may vary among the several genetic forms of a given disorder. Many examples of genetic heterogeneity have been uncovered during the past 50 years, especially through the application of biochemical and molecular methods. A striking example was homocystinuria, which simulates Marfan syndrome closely because of dislocated lenses and skeletal features such as increased height, scoliosis, and deformity of the anterior chest, but homocystinuria has recessive, not dominant, inheritance; has thrombotic, not aortic, complications in the cardiovascular system; and, of course, has a biochemical marker in the form of homocysteine in the urine.

Baur, Lenz, and Fischer, in their textbook in the 1930s, recognized genetic heterogeneity. William Allen, who is honored by the William Allen Award of the American Society of Human Genetics, wrote about genetic heterogeneity when he pointed out that some disorders, such as Charcot-Marie-Tooth disease, occur in autosomal

dominant, autosomal recessive, and X-linked forms. Allen pointed out that as a generalization the autosomal recessive form is most severe, the autosomal dominant form mildest (and most variable), and the X-linked recessive form intermediate in severity. This generalization is sometimes called Lenz’s law, after Fritz Lenz of the Baur, Lenz, and Fischer textbook (and father of Widukind Lenz, medical geneticist of Münster, Germany).

Harry Harris (133) (Figure 1-8) of London, emphasized the heterogeneity of apparently simple “characters.” One of the problems central to all studies in human genetics arises from the difficulty of knowing whether a particular difference has been characterized in, as it were, a “chemically pure” form. What appears at first sight to be a homogeneous entity readily identifiable by a particular technique, and presumably having a unitary genetical causation, turns out, with the application of newer techniques to the problem, to consist of more than one quite distinct phenomenon ... The condition known as “cystinuria” provides a simple illustration of this point.

As one aspect of the “darker side” of heredity counseling, F. Clarke Fraser (134) pointed to genetic heterogeneity of clinical entities. He wrote “A lot of difficulty comes from the fact that for many diseases two clinically similar cases may be genetically different, and thus have different genetic prognoses.”

Newton E. Morton (79) demonstrated genetic heterogeneity in elliptocytosis when he found that the disorder is linked to the Rh blood group locus in some families and not in others.

Variation in the clinical picture is a characteristic of disease of all etiologies, both genetic and nongenetic. If the clinical picture resulting from a particular etiologic factor were invariant, clinical medicine would be child’s play. Learning clinical medicine is, to a large extent, learning how to cope with variation, as well as pointing out the significance of pleiotropism, Hans Grüneberg (129) emphasized that variability can depend on the genetic background of the particular mutation. A frequently cited example from the mouse was provided by the work of L. C. Dunn (1893–1974), who found that the brachyury mutation, usually manifested by a short tail, was accompanied by an almost normal tail in some genetic stocks.

Penetrance and expressivity are aspects of variation. The terms and the concepts they signify were introduced by Vogt in 1926 (135) and were used by Timofeeff-Ressovsky soon thereafter while he was working in Berlin with Vogt. (Timofeeff-Ressovsky, still in Berlin at the time the Russians captured the city in 1944, was sent to a gulag, where he was a fellow prisoner of Solzhenitsyn; see Solzhenitsyn’s *Gulag Archipelago* for references to the evening intellectual interactions by which they helped maintain each other’s sanity. Timofeeff-Ressovsky was partially “rehabilitated” toward the end of his life and attended the World Congress of Genetics in Moscow in 1978.)

Penetrance is an all-or-none phenomenon. Expressivity is variation in severity of a genetic disorder or trait. When expressivity is so low that the disorder cannot be recognized, the gene is said to be nonpenetrant. Obviously, nonpenetrance is to some extent related to the power of the methods for studying the phenotype. The more penetrating the method, the lower the frequency of nonpenetrance.

### 1.4.8 Clinical Armamentarium of Medical Genetics

Part of the reason for the creation of the American Board of Medical Genetics and comparable agencies in some other countries is the fact that since 1956 there is so much more that clinical geneticists can do. Thus, a mechanism is needed for oversight of the training and certification of practitioners.

Bradford Hill, the British biostatistician, suggested that the practice of medicine consists of seeking answers to three questions: What is wrong? The answer is diagnosis. What is going to happen? The answer is prognosis. What can be done about it? The answer is treatment. (David Danks of Melbourne suggested to me that the health professional should always keep a fourth question in mind: Why did it happen? The answer is etiology and pathogenesis, on which prevention and treatment can be based.)

Advances in diagnosis have come from both the clinic and the laboratory. Because the individual genetic disorders, of which there are many, are rare, clinical geneticists play a key role in diagnosis. For many of these disorders, there are not yet specific biochemical or other tests. Syndromology and dysmorphology are important aspects of the clinical geneticist's work. Cytogenetic diagnosis is his specific responsibility, at least for non-malignant disorders. The oncologist makes heavy use of cytogenetic diagnosis, particularly in relation to hematologic malignancies.

Prognosis in clinical genetics has somewhat different implications than prognosis in other parts of clinical medicine. The question—What is going to happen?—relates not only to the person at hand but also to other members of the family, particularly an unborn child. Testing for the carrier status in a condition such as Duchenne muscular dystrophy or hemophilia or for a disease in its presymptomatic stages as in HD is obviously of great importance to prognostication.

Neonatal screening and population-based screening for specific genetic diseases, and prenatal screening for Down syndrome in mothers over 35 years of age, do not fit neatly into the Bradford Hill paradigm of clinical medicine. Although they do address the question—What is going to happen?—the question—What is wrong?—has not been asked. The question is not even—Is something wrong?—as all genetic disorders are not tested for.

These procedures are at the interface between clinical medicine and public health, or at least between clinical

medicine and preventive medicine. I would not wish to suggest that I recognize a distinction between preventive medicine and clinical medicine; preventive medicine is an integral and exceedingly important aspect of clinical medicine.

Treatment is generally viewed as the “short suit” of clinical genetics. However, more can be accomplished than is realized, and I would emphasize that management is a better designation for the medical geneticist's role than is treatment, which implies a repertoire of measures almost exclusively pharmaceutical or surgical.

With this overview as a preamble, let me outline the development of the medical geneticist's clinical armamentarium during the past 50 years.

An important item in the armamentarium of the clinical geneticist is command of syndromology and dysmorphology. Genetic diseases include a large number of individually rare disorders many of which have little basis of diagnosis other than their particular clinical features. Syndromology is the art and science of recognizing distinct genetic entities by characteristic combinations of clinical manifestations. Robert Gorlin of Minneapolis and John Opitz of Madison, Wisconsin (later of Helena, Montana, and Salt Lake City), are two American syndromologists from among the many capable ones. Dysmorphology is the term introduced by David W. Smith (1926–1981) of Seattle, Washington, as an improvement on clinical teratology. It implies syndromology and as well encompasses considerations of etiology and pathogenesis; for example, the mechanisms by which the several features of malformation syndrome occur together were part of David Smith's focus, and his delineation of the fetal alcohol syndrome illustrated his attention not only to distinctive clinical features but also to causation. *Smith's Recognizable Patterns of Malformation Syndromes* (136) is a classic.

Many malformation syndromes and genetic disorders carry the name of a person, not always the first, who described the condition as a distinct entity. These eponyms have advantages when the basic nature of the disorder is unknown and thus a specific label based thereon is not possible. Usefully, eponyms remind medical geneticists of the roots of their field (137). Place names (toponyms) likewise link the disorder to the geographic or ethnic setting of the first (or early) description of the disorder or protein (e.g. hemoglobin) variant. Tangier disease and familial Mediterranean fever are examples.

Neither syndromology nor dysmorphology is limited to genetic disorders, but congenital anomalies of all etiologies are the responsibility of clinical geneticists. They must keep in mind all causation, both genetic and non-genetic and an interaction of the two. It was no accident that the teratogenic action of thalidomide was detected by a medical geneticist, Widukind Lenz, in the early 1960s. It was easy for a nongeneticist to consider phocomelia a genetic disorder; a geneticist would be more likely to recognize that the distribution of cases in time, place, and families was not consistent with a genetic basis.

Annual conferences entitled the Clinical Delineation of Birth Defects were initiated in 1968 at Johns Hopkins University with financial support of the March of Dimes. During their heyday, from 1968 to about 1978, these gatherings of the aficionados illustrated the attention given by clinical geneticists to the development of the field of syndromology/dysmorphology. The annual David W. Smith conferences continue in the same tradition.

Several computerized databases have been developed during the past 10–15 years as an aid to the syndromologist: the London Dysmorphology Database of Robin Winter; GenDiag of Ségolène Amye, Paris; and POSSUM of Agnes Bankier and David Danks of Melbourne.

### 1.4.9 A Synthesis: 1956–2001

Interestingly, 1956 was not only the year that human chromosomology got off to a firm start but also the date of the First World Congress of Human Genetics, which took place in Copenhagen under the presidency of Tage Kemp. The 10th and the most recent of these quinquennial congresses was held in 2001. The first congress was a splendid survey of the status of human genetics at the time. The subsequent congresses were milestones measuring progress since 1956 (138).

At the first congress in 1956, Tjio and Levan (Figure 1-6A and B) and Ford and Hamerton (139) (Figure 1-7A and B) were getting the chromosome number right. Newton Morton was writing on linkage analysis. Oliver Smithies was beginning to write on starch gel electrophoresis. Vernon Ingram was narrowing down the molecular defect in sickle hemoglobin to a single peptide, and the first edition of my *Heritable Disorders of Connective Tissue* (130) was published.

Behold what happened between the first congress and the eighth held in Washington in 1991. From the anatomy of the chromosomes at the most elementary level of enumeration, we had gone to their dissection by both mechanical and molecular methods. Genetic linkage had enjoyed a phenomenal renaissance, and linkage was by then analyzed on populations of sperm studied individually by direct molecular methods. Rather than studying variation in proteins by electrophoresis, we were examining variation in the DNA itself. From the one example of sickle hemoglobin, the known mutational repertoire of the  $\beta$ -globin gene had expanded to more than 400, for example. At least one disease-related point mutation had been defined in more than 170 different genes, a count that had passed the 1000 mark by the end of 2000 (140).

Among the heritable disorders of connective tissue, clinical delineation had been refined by molecular definition. For example, in the mucopolysaccharidoses, lumped under the Hurler syndrome in 1956, at least 10 enzymatically distinct entities had been defined and, in the disorders of the fibrous elements of connective tissue, precise intragenic lesions had been described in

osteogenesis imperfecta, in some of the Ehlers–Danlos syndromes and skeletal dysplasias, and in the Marfan syndrome.

By the 1961 congress in Rome, chaired by Luigi Gedda, clinical chromosomology had arrived. From the findings in Turner syndrome and Klinefelter syndrome, the role of the Y chromosome in sex determination was realized; the existence of testis-determining factor (TDF) was deduced. The hypothesis of the single-active X chromosome, advanced by Mary Lyon (141,142) (Figure 1-33), was the intellectually provocative new concept. Electrophoretic polymorphisms of serum proteins and red cell enzymes were being described. The “Philadelphia chromosome” was found in chronic myelogenous leukemia, one of the first pieces of evidence in humans supporting the chromosome theory of cancer (18).

By 1991, imprinting had taken the place of lyonization. TDF had been cloned and characterized under the label “sex-determining region of Y.” The fundamental basis of specific forms of cancer had been traced to specific genes—sometimes multiple, sequentially collaborating genes—and to specific mutations within genes.

The Chicago congress in 1966 was under the presidency of Lionel S. Penrose of London (Figure 1-20). The genetic code had been completely deciphered that year. Somatic cell genetics had entered the scene for the study of inborn errors of metabolism. For example, it provided the strongest proof of the Lyon hypothesis and, through the study of cultured amniotic cells, opened the way for prenatal diagnosis by amniocentesis. The concept of lysosomal diseases had emerged, and the first edition of *Mendelian Inheritance in Man* (MIM) (143), already computer based, was published earlier that year.

Review of the growth of successive editions of MIM provides an opportunity to engage in some scientometrics. As indicated by the original subtitle “Catalogs

**FIGURE 1-33** Mary Lyon (center) with Wesley Whitten at Bar Harbor, 1971.

of Autosomal Dominant, Autosomal Recessive, and X-linked Phenotypes,” MIM was an encyclopedia of phenotypes—genetic traits and disorders. But early on it was the intent that there should be one entry per gene locus, based largely on the philosophy that, if two genetic diseases or traits result from mutation at different loci, they are fundamentally distinct, however similar in phenotype they may be. Genetics is finding genes—gene hunting. The number of entries in successive editions of MIM can serve as one basis of quantifying progress in our field in the past 40 years. There were about 1500 entries in the first edition. In the 1960s, the only way we had to identify separate entries (read “gene loci”) was by mendelizing phenotypes, sometimes aided by biochemical or immunologic characteristics or by genetic features such as linkage. In the 1970s, the rate of accession was accelerated by a parasexual method for gene identification and mapping, namely, somatic cell hybridization. By the 1980s, cloning of human genes was practiced. Accordingly, entries in MIM were created for genes when they were cloned, sequenced, and mapped, even though no Mendelian phenotype had been associated. By the 12th edition (144), entries in MIM numbered 8587, an impressive figure but still a long way from the 60,000 to 70,000 expressed genes the human was then thought to have (145). (By fall 2000, the number in the continuously updated online version, OMIM, was approaching 12,000.) Furthermore, by the 1990s, the evolution of the content of MIM as outlined above had led to a self-redefinition that prompted change of the subtitle to “*A Catalog of Human Genes and Genetic Disorders*” in the 11th edition (1994) and thereafter.

By the Paris congress in 1971, the study of inborn errors of metabolism in cultured cells had paid off. For example, elucidation of the defect in Lesch–Nyhan syndrome and the differentiation of various mucopolysaccharidoses had been accomplished through the study of cultured cells. Chromosome banding had been introduced, and the first genes were being assigned to specific autosomes by linkage to chromosomal heteromorphisms and rearrangements and by interspecies somatic cell hybridization. There were four autosomal gene assignments by 1971.

Plotting the growth of the human gene map since 1971 is another exercise in scientometrics. By June 1976, just before the fifth congress in Mexico City, at least one gene had been assigned to every chromosome. This was largely through the application of somatic cell hybridization. By the 1981 congress in Jerusalem, molecular genetic methods for gene mapping had entered the scene and were responsible for further acceleration of mapping in the 1980s. Molecular genetics provided probes for identification of human genes in rodent/human somatic cell hybrids. It provided probes for in situ hybridization to chromosomes and, importantly, it provided DNA markers (e.g. RFLPs, VNTRs) for family linkage studies, for mapping Mendelian disorders of unknown biochemical basis. By the time of the 1991 congress, a total of at

least 2300 genes had been mapped to specific chromosomes and, for most, to specific chromosomal regions.

By the fifth congress in Mexico City in 1976, other advances of note included the concept of receptor diseases—disorders such as familial hypercholesterolemia (146) and androgen insensitivity—and the Knudson hypothesis of hereditary/sporadic tumors (49,147). The Philadelphia chromosome had been reinterpreted as a reciprocal translocation rather than a deletion.

By the 1981 congress in Jerusalem, under the presidency of James V. Neel (Figure 1-34), in addition to the advances in the methods and results of gene mapping, human genes were being cloned, the genetic basis of antibody diversity was well on the way to elucidation, human variation was being studied with monoclonal antibodies, and one human chromosome had been completely sequenced—the mitochondrial chromosome.

By 1986 and the congress in Berlin, presided over by Arno Motulsky (Figure 1-34), HD had been mapped using RFLPs—the first disorder of unknown biochemical basis mapped by this approach. VNTRs were a new class of markers. The previous spring, PCR had been unveiled at the Cold Spring Harbor Symposium, which had been devoted to the human genome. PFGE, DGGE, and CVS were introduced as acronyms for other new techniques or diagnostic methods. Contiguous gene syndromes were conceptualized and the deletions underlying them used for gene mapping and gene isolation. The approach, then called “reverse genetics,” had succeeded in isolation of the gene for chronic granulomatous disease and at the very time of the congress was well on the way to characterization of the large gene that is mutant in Duchenne muscular dystrophy. Transgenic mice expressing human genes had been created. By molecular methods, the Knudson hypothesis had been proved for retinoblastoma; and the specific oncogenic molecular changes in the Philadelphia chromosome of chronic myeloid leukemia had been worked out, as well as those in the translocations underlying Burkitt lymphoma.

**FIGURE 1-34** Three presidents of the World Congress of Human Genetics (left to right): Arno Motulsky (Berlin, 1986), James V. Neel (Jerusalem, 1981), Victor McKusick (Washington, 1991). Photo from 1991. Neel died in 2000 at the age of 85.

By the time of the eighth congress in 1991 (chaired by Victor McKusick; Figure 1-34), the HGP had been launched. The HGP had been in a stage of debate and planning in 1986. The fruitfulness of positional cloning (alias reverse genetics) had been established for Duchenne muscular dystrophy, cystic fibrosis, neurofibromatosis, polyposis coli, and others. The candidate gene approach had also paid off for retinitis pigmentosa, hypertrophic cardiomyopathy, Marfan syndrome, and malignant hyperthermia. The genetics of common cancers such as colon cancer had been greatly clarified. TDF had been cloned. Specific mutations in the mitochondrial chromosome had been related to specific diseases. Imprinting and uniparental disomy were challenging concepts.

Between the eighth congress and the ninth (1996), in Rio de Janeiro, Brazil, with Newton Morton as president, ESTs (expressed sequence tags) were introduced (148) as a shortcut to the expressed part of the genome, the first free-living organism (*H. influenzae*) was completely sequenced (1995), a detailed linkage reference map using DNA markers was completed, a physical map of YAC contigs was published, radiation hybrid mapping came into wide use, the role of folic acid in birth defects was accepted as established and folic acid supplementation of food products introduced into practice. Preimplantation diagnosis at a four- or eight-cell stage was added to in vitro fertilization (IVF), as a method for selection of non-mutant concepti.

Between the ninth congress in Rio de Janeiro and the 10th in Vienna in 2001 (G. Utermann, president), database “mining” (research in silico or cybergenomics) came in as a primary method of genomic research. As a result of positional cloning and related approaches to disease gene discovery, well over 1000 genes had been found to have one or more disease-related mutations (140). Microassay methods (chip technology) had been introduced for profiling gene expression and for gene diagnosis (149). Yeast became the first eukaryote to be completely sequenced (in spring 1996 shortly before the Rio congress). *Caenorhabditis elegans*, a nematode, was the first metazoan completely sequenced (in 1999), followed by *Drosophila* (in 2000). On June 26, 2000, completion of a first draft of the complete human sequence was announced jointly by Venter and Collins, for the private and public projects, respectively, in a historic ceremony in the East Room of the White House, with connection by satellite to 10 Downing Street in London where Prime Minister Blair echoed President Clinton in emphasizing the significance of the event.

During the 1996–2001 interval, rapid progress toward the goal of the HGP was accompanied by the following paradigm shifts:

- from structural genomics to functional genomics;
- from map-based gene discovery to sequence-based gene discovery;
- from genetic disease diagnosis to detection of genetic predisposition of common disorders;
- from etiology (specific causation) to pathogenesis (mechanism);
- from a one-gene-at-a-time approach to study of systems, pathways, and families of genes;
- from genomics to proteomics.

Another paradigm shift was from medical genetics to genetic medicine. This was not merely a change of name of institutions, although that did occur, as in the program at Johns Hopkins, which began in 1957 as the Division of Medical Genetics in the Department of Internal Medicine, became in 1989 a multidisciplinary Center for Medical Genetics, and in 1999 was transformed into an institute of genetic medicine. Beyond a change in name, this shift is a broadening of perspective. Medical genetics tends to imply an exclusive focus on rare Mendelian disorders and chromosomal aberrations; genetic medicine reflects the fact that genetics pervades all parts of clinical medicine, that genetic factors are involved in all disease, and that genetic predisposition in the etiology of common disorders (complex traits) is an important part of the science and practice of medical genetics.

Since 1956, human genetics has become medicalized, to use Motulsky’s term, to an enormous extent. It has become subspecialized. Medical genetics has become professionalized through the development of clinical colleges and certifying organizations. During the past decade, human genetics has also become intensely molecularized. Molecular genetics pervades all aspects of human and medical genetics. Human genetics has become commercialized to an extent we might not have predicted. The field has also become democratized and universalized; its implications are felt in all aspects of society. It has become consumerized; consumerism is evident in the role of genetic support groups and foundations for funding of research on single genetic diseases.

#### 1.4.10 Forty Years in the History of Medical Genetics

*Mendelian Inheritance in Man* (MIM) has recorded in detail the advances in medical genetics in the period since it was first initiated in 1960 as a catalog of X-linked traits (126). The catalog of recessives was undertaken in late 1962 in connection with studies of an inbred group, the Old Order Amish. The dominant catalog was created in 1963. The catalogs were placed on the computer in 1964. The first print edition of all three catalogs (a pioneer in computer-based publication) appeared in 1966, the 12th in 1998. The 12 editions represent serial cross-sections of the field of medical genetics over four decades.

MIM was made publicly available online (under the designation OMIM) in 1987. OMIM (<http://www.ncbi.nlm.nih.gov/omim>) has the virtue of timeliness (it is updated

almost daily) and easy searchability. The print version has usefulness in a nonelectronic setting and as an archive.

The evolution of medical genetics since the early 1960s is illustrated in many ways by MIM (and OMIM). The subtitle at the beginning was “*Catalogs of Autosomal Dominant, Autosomal Recessive, and X-linked Phenotypes*.” Although the gene behind the phenotype was always in mind (e.g. the X-linked catalog was created as an indication of the genetic constitution of the X chromosome), almost the only way to identify a gene was through a mendelizing phenotype, at the beginning. With molecular genetic advances, the subtitle in later print editions became “*A Catalog of Human Genes and Genetic Disorders*.”

## 1.5 THE FUTURE

Since the late 1980s, thought and discussion have been devoted to the future of human genetics to an unprecedented extent—largely growing out of the debate over the HGP and the planning for it. Rarely, if ever, has the future of a scientific field and its implications for society been given such wide and intense attention. An unusual and important feature of the federally funded HGP in the United States was support of research projects in the ethical, legal, and societal implications (ELSI) of genome mapping and sequencing.

ELSI was a proactive effort to avoid misuse and abuse of newfound genomic information. The history of eugenics and its misguided, unethical, and immoral practices based on primitive knowledge of human genetics in the first half of the twentieth century was a warning signal. The atrocities in Nazi Germany (150) were only the most flagrant, inhuman, and abominable examples. Furthermore, it was anticipated that the power of information on the full genome of individuals and population groups would raise novel issues for society, medicine, and the law.

Completion of the HGP provides a source book of the human that will be the basis for study in human biology and medicine for a long time to come. When all the genes have been found, we certainly still will not know, for most of them, their function even in solo, let alone in concert with the rest of the genome. True reverse genetics, in the New Genetics according to Walter Gilbert, David Botstein, and others, will involve working from specific DNA sequences of unknown function to the phenotype. Having in the past 35 years worked progressively from the phenotype to DNA, we will in the next 35 years be returning from DNA to the phenotype by determining the function of specific DNA sequences. Just as the function of much of the DNA remains to be determined even though the full sequence is known, the worldwide variation in that DNA is largely unknown, and long study will be required of the relationship between DNA variation and variation in function, critical to the understanding of evolution and the genetics of disease susceptibility and performance.

Study of the source book provided by the HGP should be particularly useful in the two great frontiers of human biology: how the mind works and how development is programmed. In the area of health and medicine, great benefit can be expected from the better understanding of genetic factors in multifactorial disorders, which tend to be the common conditions such as hypertension and major mental illness. The source book will surely be very useful to the understanding of somatic cell genetic disease. Gene mapping and related studies have been primarily responsible for appreciation that in addition to the three classical categories of genetic disease—single gene disorders, multifactorial disorders, and chromosomal aberrations—somatic cell genetic disease is a large fourth category. This has been most extensively and definitively established through the definition of mutation as the basis of cancer. (Facetiously, it is suggested that medical genetics is taking over oncology.) Somatic cell mutations are likely to occupy us increasingly as the basis of congenital malformations, autoimmune processes, and even aging. (McFarlane Burnett suggested about 1960 that somatic cell mutation is the basis of autoimmune processes, and a somatic mutation theory of aging has been entertained for a long time.) The connection between oncogenesis and teratogenesis—between oncogenes and teratogenes, if you will—is already adumbrated by the examples of Wilms’ tumor and Greig cephalosyndactyly syndrome, to mention two. It is to be assumed that somatic cell gene therapy not only for inherited diseases but perhaps also for some of these acquired somatic cell genetic diseases, especially neoplasia, will become available during the next decade.

Two scientific and technologic revolutions, the biologic revolution and the information revolution, converged in the human genome initiative. Information is power. Risks can accompany both the political and the scientific changes. Appropriately, ethical, legal, and societal implications of the human genome initiative are being examined in many parts of the world.

The methods developed by the HGP will allow the rapid and economical generation of information on the genomes of individuals. In the medical area, this information will widen the gap between what we know how to diagnose and what we know how to treat, between what we can diagnose in the presymptomatic state and what we can prevent. We have had that problem, for example, in the case of HD. The complete map and sequence are also likely to increase the gap between what we think we know and what we really know. But by this second gap, I refer in part to the likelihood that weak associations will be found between particular genomic constitutions and certain presumed characteristics such as criminality or alcoholism or elements of intelligence or performance. Some of these associations are likely to be spurious. Other weak associations may be found to be statistically valid but will be blown out of all proper proportion to the detriment of individuals

and of groups. As geneticists, we have a responsibility to avoid unfounded conclusions and overblown interpretations and to inculcate the profound respect for the genetic variability that is the strength of the species and indeed of the individual—referring to the differences in the two genomes each of us has, one from the father and one from the mother.

The mere existence of the complete reference gene map and DNA sequence down to the last nucleotide may lead to the absurdity of reductionism, the misconception that we then know everything it means to be human, or to the absurdity of genetic determinism, that what we are is a direct and inevitable consequence of what our genome is. Our phenotypes are not “hard-wired” to our genotypes. Risk figures that state the chance of given common disorder in an individual based on a genome screen are probabilities, not certainties. They are more analogous to a weather report than to a road map.

Thus, information on the reference gene map and sequence of the human may represent per se a hazard, if it distorts the way we think about ourselves and our fellow human beings. The ability to analyze the genomes of individuals is accompanied by risks of information misuse and abuse. We must be alert to the need to protect the privacy and confidentiality of the information that the HGP will allow to be collected on the genetic constitution of individuals. We must make every effort to avoid the misuse or abuse of such information by third parties, and our governments may need to take measures to assure these protections under law.

Near the end of his terms of office, President Eisenhower warned against the dangers of the military industrial complex. It is appropriate to warn of a potential hazard of the genetic–commercial complex. The increasing availability of tests for presumed genetic quality or poor quality could lead the commercial sector and the Madison Avenue publicist to bring subtle or not so subtle pressure on couples to make value judgments in the choice of their gametes for reproduction. Autonomy in reproductive choice is a cornerstone of the ethics of genetic counseling. That reproductive choice would not be autonomous if subjected to the Madison Avenue type of pressure. Especially, trivialization of reproductive choices should be avoided.

As human geneticists, we are privileged to work in a scientifically important field and a field of intellectual challenge. Human genetics is a field that holds particular fascination because it involves the most fundamental and pervasive aspects of our own species, an added fascination that the physical sciences or pure mathematics, for example, cannot share. To have combined with this intellectual and anthropocentric fascination the opportunity to contribute to human welfare and to be of service to families and individuals through medical genetics and clinical genetics is a privilege. The privilege carries with it responsibilities to which I have already referred.

## 1.6 ADDENDUM (PSH)

### 1.6.1 The Founders of Clinical Genetics

The section headed “the evolution of Clinical Genetics” in McKusick’s original chapter tells us much about the advances in the field over the past half century, but almost nothing about the people responsible or the pattern of evolution across different countries. Perhaps this is not too surprising, for he would have unavoidably had to give much prominence to himself. Now there need not be any such inhibitions and an account, necessarily brief, of the founders of the field forms an important part of its history.

While there were medically trained researchers in human genetics from the beginning of the twentieth century, such as Julia Bell in Britain (105) and Madge Macklin and William Allan in America (Soltan, 1992), Clinical Genetics as a medical discipline did not take shape in any significant way until the 1950s, when medical workers in several countries began to recognize that the scientific foundations of human genetics were now substantial enough for the systematic development of both clinically oriented research and genetic services.

In North America the initial step can be seen as the founding in 1950 of a medical genetics unit at Montreal Children’s Hospital by F. Clarke Fraser, followed in 1957 by academic departments (technically Divisions of Departments of Medicine) in Baltimore and Seattle, by Victor McKusick and Arno Motulsky, respectively. In Europe, France took an early lead, with Pediatrician Maurice Lamy appointed as Professor of Medical Genetics at Hôpital Necker, Paris in 1953, succeeded by Jean Frézal. Britain, in the form of Lionel Penrose’s Galton Laboratory at University College, London, had provided a focal point from 1945 for training and inspiring many of the founders from elsewhere, but did not itself develop as a clinical genetics unit, concentrating on basic human genetics research after Penrose’s retirement, while John Fraser Roberts, active from the 1930s and founding the first UK genetic counseling clinic in 1948, also restricted his clinical role to genetic counseling alone, as did his successor Cedric Carter. The two major British founders in the field of clinical genetics were Pediatrician Paul Polani, based at Guy’s Hospital, London, and Cyril Clarke, internist and head of Medicine at the Liverpool Medical School. It is of interest to note that the medical background of these founders in both Britain and North America was at least as much from adult medicine as from pediatrics.

In many countries, development of clinical genetic services was considerably slower; for Germany this is not unexpected, given the legacy of abuses from eugenics under the third Reich, but it is more surprising in the case of the Scandinavian countries, which had from an early stage been leaders in human genetics research. From the very beginning, though, close international links have

been a strong feature of medical genetics, encouraged and reinforced by the numerous visiting workers at Penrose's Galton Laboratory and by the trainees from many different countries with Victor McKusick in Baltimore, most of whom became leaders in their own countries on their return and were strongly influential in determining the pattern and ethos of genetic services which they and their successors established.

### 1.6.2 Victor McKusick and the History of Medical Genetics

The role of Victor McKusick in the history of Medical Genetics is a threefold one. As a key founder of the field, he and his own work, over a period of more than 50 years (114), form a major strand in its history and development; secondly, his periodic reviews on the current status of medical genetics chronicle successive advances ((126); Mckusick, 1989) and many of his other writings have a strongly historical approach. Finally from the beginning of his career he took a keen interest in the history of medicine and published a series of studies on specific physicians whose early reports formed important landmarks in the documentation of inherited disorders (143). A fuller assessment of McKusick's role as a historian of Medical Genetics can be found in the chapter by Harper in the book of Dronamraju and Francomano (2012).

Another, more unusual contribution has come from McKusick's habit of taking numerous photographs at conferences, courses and all other possible occasions, both formal and informal. Many of the then young and unknown scientists and clinicians who appear in these informal "snaps" have since risen to fame. This collection must amount to several thousand images over the years and it is greatly to be hoped that they will be carefully preserved and cataloged along with his other personal scientific records at the Johns Hopkins Archive.

Only a few have been published, some in this chapter, others in relation to the Bar Harbor "short course" on medical genetics (1).

Altogether medical genetics is fortunate to have had such an assiduous and objective chronicler of its first half century as Victor McKusick has been.

### 1.6.3 Preserving the History of Medical Genetics

The inevitable loss of the founders of Medical Genetics reminds us how much of its history we lose when they die. Not all of the key workers have such a keen historical sense as did Victor McKusick; many confine their writing to current scientific or clinical activities. The records of past discoveries, like old personal scientific records and correspondence, are often destroyed or lost, while increasingly, older workers continue with their research up to an advanced age and give less thought to documenting or reflecting on their past achievements.

For these and other reasons a coordinated effort is required if the history of medical genetics is to be fully recorded for posterity, rather than future historians being left with a few, perhaps unrepresentative, fragments on which to base their future analyzes. Fortunately, it is not too late for much to be salvaged, and several significant initiatives have already been started, both in Europe and America. Table 1-2 lists some of these; increasingly they are web-based, making the end results accessible to all. Oral history, as well as written records, forms a key element, especially recorded interviews with early workers in the field.

At the same time though, the pace at which "current advances" turn into "history" is quickening, so it is essential that documenting the history of a particular area begins as early as possible; a prime example is the HGP, but the beginnings of human molecular genetics in medicine are likely to be of equal significance.

**TABLE 1-2 History of Human and Medical Genetics Sources and Resources**

#### Records of individual workers

American Philosophical Society Genetics Collection (APS) (<[www.amphilsoc.org](http://www.amphilsoc.org)>).

UK Genetics Archive Project (<[www.genmedhist.org/Records](http://www.genmedhist.org/Records)>).

Cold Spring Harbor Archive (<<http://library.cshl.edu/>>).

#### Oral history

Oral history of human genetics project (<[www.socgen.ucla.edu/hgp/](http://www.socgen.ucla.edu/hgp/)>).

Interviews with human and medical geneticists (<<http://www.genmedhist.org/Interviews>>).

*Talking of Genetics* (Gitschier, 2010)

Witness Seminars. See <[www.ucl.ac.uk/histmed/publications/wellcome\\_witnesses\\_c20th\\_med](http://www.ucl.ac.uk/histmed/publications/wellcome_witnesses_c20th_med)> for the transcripts of several seminars relevant to medical genetics.

#### Books

See "Further reading"; also Harper (2008), Chapter 18 and Appendix 1 for details.

#### Book collections

Human Genetics Historical Library (see <<http://www.genmedhist.org/HumanHistLib/>>). A collection of over 3000 books.

Electronic Scholarly Publishing (<[www.esp.org](http://www.esp.org)>) has digitized a series of books and papers on classical genetics.

Cold Spring Harbor Laboratory Press has published a number of important historical books on genetics and eugenics.

## 1.7 A TIMELINE FOR MEDICAL GENETICS

Modern medical genetics as a well-defined field of medicine has developed so rapidly since its beginnings half a century ago, that it is often forgotten how far back in time its roots and origins go (Table 1-3). It can be reasonably argued that genetics overall was based in considerable measure on problems of human inheritance and inherited disease, and studies of this extend back long before the twentieth century acceptance of Mendelism. Thus medical genetics, when thought of in the

widest sense, is perhaps the oldest area of genetics, and certainly not the recent addition that it is sometimes portrayed as.

This “timeline” gives some of what I consider to be the main landmarks along this lengthy course. Not all of these can be considered to be directly part of “medical genetics,” even on the broadest definition, but they are all relevant to it in one way or another. I have also included some more general “world events” that have particularly impacted on the development of the field. I shall welcome suggestions for other items that might be included in future updates.

**TABLE 1-3 A Timeline for Human and Medical Genetics. Based on the Timeline of the Genetics and Medicine Historical Network (<[www.genmedhist.org](http://www.genmedhist.org)>). The Original Version First Appeared in Harper PS (2008): A Short History of Medical Genetics, OUP**

1651	William Harvey's book <i>De Generatione Animalium</i> studies the egg and early embryo in different species and states: “Ex ovo omnium” (all things from the egg).
1677	Microscopic observations of human sperm (Leeuwenhoek).
1699	Albinism noted in “Moskito Indians” of Central America (Wafer)
1735	Linnaeus, <i>Systema Naturae</i> . First “natural” classification of plants and animals.
1751	Maupertuis proposes equal contributions of both sexes to inheritance and a “Particulate” concept of heredity.
1753	Maupertuis describes polydactyly in Ruhe family; first estimate of likelihood for it being hereditary.
1794	John Dalton. Color blindness described in himself and others. Limited to males. Erasmus Darwin publishes <i>Zoonomia</i> . Progressive evolution from primeval organisms recognized.
1803	Hemophilia in males and its inheritance through females described (Otto).
1809	Inherited blindness described in multiple generations (Martin). Lamarck supports evolution, including man, based on inheritance of acquired characteristics.
1814	Joseph Adams, Concepts of “predisposition” and “disposition”; “congenital” and “hereditary.”
1852	First clear description of Duchenne muscular dystrophy (Meryon).
1853	Hemophilic son, Leopold, born to Queen Victoria in England.
1858	Charles Darwin and Alfred Russel Wallace. Papers to Linnean Society on Natural Selection.
1859	Charles Darwin publishes <i>On the Origin of Species</i> .
1865	Gregor Mendel's experiments on plant hybridization presented to Brunn Natural History Society.
1866	Mendel's report formally published.
1868	Charles Darwin's “provisional hypothesis of pangenesis.” Charles Darwin collects details of inherited disorders in <i>Animals and Plants under Domestication</i> .
1871	Friedrich Miescher isolates and characterizes “nucleic acid.”
1872	George Huntington describes “Huntington's disease.”
1882	First illustration of human chromosomes (Flemming).
1885	“Continuity of the germ plasm” (August Weismann).
1887	Boveri shows constancy of chromosomes through successive generations.
1888	Waldeyer coins term “chromosome.” Weismann presents evidence against inheritance of acquired characteristics.
1889	Francis Galton's <i>Law of Ancestral Inheritance</i> .
1891	Henking identifies and names “X chromosome.”
1894	Bateson's book <i>Material for the Study of Variation</i> .
1896	EB Wilson's book <i>The Cell in Development and Inheritance</i> .
1899	Archibald Garrod's first paper on alkaptonuria.
1900	Mendel's work rediscovered (deVries, Correns and Tschermak).
1901	Karl Landsteiner discovers ABO blood group system. Archibald Garrod notes occurrence in sibs and consanguinity in alkaptonuria.
1902	Bateson and Saunders' note on alkaptonuria as an autosomal recessive disorder. Bateson and Garrod correspond. Garrod's definitive paper on alkaptonuria an example of “chemical individuality.” Bateson's <i>Mendel's Principles of Heredity</i> . A <i>Defence</i> supports Mendelism against attacks of biometricians. Chromosome theory of heredity (Boveri, Sutton).
1903	American Breeders Association formed. Includes section of eugenics from 1909. Cuénot in France shows Mendelian basis and multiple alleles, for albinism in mice. Castle and Farabee show autosomal recessive inheritance in human albinism. Farabee shows autosomal dominant inheritance in brachydactyly.

*Continued*

**TABLE 1-3 A Timeline for Human and Medical Genetics. Based on the Timeline of the Genetics and Medicine Historical Network (<[www.genmedhist.org](http://www.genmedhist.org)>). The Original Version First Appeared in Harper PS (2008): A Short History of Medical Genetics, OUP—cont'd**

1905	Stevens and Wilson separately show inequality of sex chromosomes and involvement in sex determination in insects. Bateson coins term "genetics."
1906	First International Genetics Congress held in London.
1908	Garrod's Croonian lectures on "inborn errors of metabolism." Royal Society of Medicine, London, "Debate on Heredity and Disease." Hardy and Weinberg independently show relationship and stability of gene and genotype frequencies (Hardy–Weinberg equilibrium).
1909	Bateson's book <i>Mendel's Principles of Heredity</i> documents a series of human diseases following Mendelian inheritance. Karl Pearson initiates <i>The Treasury of Human Inheritance</i> . Wilhelm Johannsen introduces term "gene."
1910	Thomas Hunt Morgan discovers X-linked "white eye" <i>Drosophila</i> mutant. Eugenics Record Office established at Cold Spring Harbor under Charles Davenport.
1911	Wilson's definitive paper on sex determination shows X-linked inheritance for hemophilia and color blindness.
1912	Winiwarter proposes diploid human chromosome number as approximately 47. First satisfactory human chromosome analysis. First International Eugenics congress (London).
1913	Alfred Sturtevant constructs first genetic map of <i>Drosophila</i> X-chromosome loci. American Genetics Society formed as successor to American Breeders Association.
1914	Boveri proposes chromosomal basis for cancer. (Outbreak of World War I).
1915	Haldane et al. show first mammalian genetic linkage in mouse.
1916	Relationship between frequency of a recessive disease and of consanguinity (F. Lenz). Calvin Bridges shows non-disjunction in <i>Drosophila</i> .
1918	Anticipation first recognized in myotonic dystrophy (Fleischer). R.A. Fisher shows compatibility of Mendelism and quantitative inheritance.
1919	Hirszfeld and Hirszfeld show ABO blood group differences between populations. Genetical Society founded in UK by William Bateson.
1922	Inherited eye disease volumes of <i>Treasury of Human Inheritance</i> (Julia Bell).
1923	Painter recognizes human Y chromosome; proposes human diploid chromosome number of 48.
1927	Hermann Muller shows production of mutations by X-irradiation in <i>Drosophila</i> . Compulsory sterilization on eugenic grounds upheld by courts in America (Buck v. Bell).
1928	Stadler shows radiation-induced mutation in maize and barley. Griffiths discovers "transformation" in <i>Pneumococcus</i> .
1929	Blakeslee shows effect of chromosomal trisomy in <i>Datura</i> , the thorn apple.
1930	R.A. Fisher's <i>Genetical Theory of Natural Selection</i> . Beginning of major Russian contributions to human cytogenetics. Haldane's book <i>Enzymes</i> attempts to keep biochemistry and genetics linked.
1931	Archibald Garrod's second book <i>Inborn Factors in Disease</i> . UK Medical Research Council establishes Research Committee on Human Genetics (Chairman J.B.S. Haldane).
1933	Nazi eugenics law enacted in Germany.
1934	Fölling in Norway discovers phenylketonuria (PKU). <i>Treasury of Human Inheritance</i> volume on Huntington's disease (Julia Bell). O.L. Mohr's book <i>Genetics and Disease</i> . Mitochondrial inheritance proposed for Leber's optic atrophy (Imai and Moriwaki, Japan).
1935	First estimate of mutation rate for a human gene (hemophilia; J.B.S. Haldane). A preliminary estimate had been made by Haldane in 1932. R.A. Fisher (amongst others) suggests use of linked genetic markers in disease prediction.
1937	First human genetic linkage—hemophilia and color blindness (Bell and Haldane). Moscow Medical Genetics Institute closed; director Levit and others arrested and later executed. Destruction of Russian genetics begins. Seventh International Genetics Congress, Moscow canceled. Max Perutz begins crystallographic studies of hemoglobin in Cambridge.
1938	Lionel Penrose publishes "Colchester Survey" of genetic basis of mental handicap.
1939	Seventh International Genetics Congress held in Edinburgh. "Geneticists' Manifesto" issued. (Outbreak of World War II) Cold Spring Harbor Eugenics Record Office closed. Rh blood group system discovered (Landsteiner and Wiener).
1941	Beadle and Tatum produce first nutritional mutants in <i>Neurospora</i> and confirm "one gene—one enzyme" principle. Charlotte Auerbach discovers chemical mutagens in Edinburgh (not published until the end of the war).
1943	Nikolai Vavilov, leader of Russian genetics, dies in Soviet prison camp. First American genetic counseling clinic. Mutation first demonstrated in bacteria (Luria).

**TABLE 1-3 A Timeline for Human and Medical Genetics. Based on the Timeline of the Genetics and Medicine Historical Network (<[www.genmedhist.org](http://www.genmedhist.org)>). The Original Version First Appeared in Harper PS (2008): A Short History of Medical Genetics, OUP—cont'd**

1944	Schrödinger's book <i>What Is Life?</i> provides inspiration for the first molecular biologists. Avery shows bacterial transformation is due to DNA, not protein.
1945	Lionel Penrose appointed as head of Galton Laboratory, London, founds modern human genetics as a specific discipline. (Hiroshima and Nagasaki atomic explosions.) Genetic study of effects of radiation initiated on survivors of the atomic explosions (J.V. Neel director).
1946	Penrose's inaugural lecture at University College, London, uses PKU as paradigm for human genetics. John Fraser Roberts begins first UK genetic counseling clinic in London. Sexual processes first shown in bacteria (Lederberg).
1948	Total ban on all genetics (including human genetics) teaching and research in Russia. American Society of Human Genetics founded. H.J. Muller, President. J.B.S. Haldane suggests selective advantage in thalassemia due to malaria.
1949	<i>American Journal of Human Genetics</i> begun. Charles Cotterman, first editor. Linus Pauling et al. show sickle-cell disease to have a molecular basis. J.V. Neel shows it to be recessively inherited. Barr and Bertram (London, Ontario) discover the sex chromatin body.
1950	Curt Stern's Book <i>Human Genetics</i> . Frank Clark Fraser initiates Medical Genetics at McGill University, Montreal.
1951	Linus Pauling shows triple helical structure of collagen. HELA cell line established from cervical cancer tissue of Baltimore patient Henrietta Lacks.
1952	First human inborn error shown to result from enzyme deficiency (glycogen storage disease type 1, Cori and Cori). Rosalind Franklin's X-ray crystallography shows helical structure of B form of DNA.
1953	Model for structure of DNA as a double helix (Watson and Crick). Bickel et al. initiate dietary treatment for PKU. Enzymatic basis of PKU established (Jervis). Specific chair in Medical Genetics founded (first holder Maurice Lamy, Paris).
1954	Allison proves selective advantage for sickle-cell disease in relation to malaria.
1955	Sheldon Reed's book <i>Counselling in Medical Genetics</i> . Oliver Smithies develops starch gel electrophoresis for separation of human proteins. Fine structure analysis of bacteriophage genome (Benzer).
1956	Tjio and Levan show normal human chromosome number to be 46, not 48. First International Congress of Human Genetics (Copenhagen). Amniocentesis first validated for fetal sexing in hemophilia (Fuchs and Riis).
1957	Ingram shows specific molecular defect in sickle-cell disease. Specific Medical Genetics departments opened in Baltimore (Victor McKusick) and Seattle (Arno Motulsky).
1958	First HLA antigen detected (Dausset).
1959	Harry Harris' book <i>Human Biochemical Genetics</i> Perutz completes structure of hemoglobin. First human chromosome abnormalities identified in: Down's syndrome (Lejeune et al.). Turner syndrome (Ford et al). Klinefelter syndrome (Jacobs and Strong).
1960	Trisomies 13 and 18 identified (Patau et al. and Edwards et al.). First edition of <i>Metabolic Basis of Inherited Disease</i> . Role of mRNA recognized. First specific cytogenetic abnormality in human malignancy (Nowell and Hungerford, "Philadelphia chromosome"). Chromosome analysis on peripheral blood allows rapid development of diagnostic clinical cytogenetics (Moorhead et al.). Denver conference on human cytogenetic nomenclature. First full UK Medical Genetics Institute opened (under Paul Polani, Guy's Hospital, London). First Bar Harbor course in Medical Genetics, under Victor McKusick.
1961	Prevention of rhesus hemolytic disease by isoimmunization (Clarke et al., Liverpool). Mary Lyon proposes X-chromosome inactivation in females. Cultured fibroblasts used to establish biochemical basis of galactosemia (Krooth and Weinberg), establishing value of somatic cell genetics. "Genetic Code" linking DNA and protein established (Nirenberg and Matthaei).
1963	Population screening for PKU in newborns (Guthrie and Susi).
1964	Ultrasound used in early pregnancy monitoring (Donald). First journal specifically for medical genetics ( <i>Journal of Medical Genetics</i> ). Genetics restored as a science in USSR after Nikita Khrushchev dismissed. First HLA workshop (Durham, North Carolina).
1965	High frequency of chromosome abnormalities found in spontaneous abortions (Carr, London, Ontario). Human-rodent hybrid cell lines developed (Harris and Watkins).

Continued

**TABLE 1-3 A Timeline for Human and Medical Genetics. Based on the Timeline of the Genetics and Medicine Historical Network (<[www.genmedhist.org](http://www.genmedhist.org)>). The Original Version First Appeared in Harper PS (2008): A Short History of Medical Genetics, OUP—cont'd**

1966	First chromosomal prenatal diagnosis (Steele and Breg). First edition of McKusick's <i>Mendelian Inheritance in Man</i> . Recognition of dominantly inherited cancer families (Lynch).
1967	Application of hybrid cell lines to human gene mapping (Weiss and Green).
1968	First autosomal human gene assignment to a specific chromosome (Duffy blood group on chromosome 1) by Donahue et al.
1969	First use of "Bayesian" risk estimation in genetic counseling (Murphy and Matalik). First Masters degree course in genetic counseling (Sarah Lawrence College, New York).
1970	Fluorescent chromosome banding allows unique identification of all human chromosomes (Zech, Caspersson et al.).
1971	"Two-hit" hypothesis for familial tumors, based on retinoblastoma (Knudson). Giemsa chromosome banding suitable for clinical cytogenetic use (Seabright). First use of restriction enzymes in molecular genetics (Danna and Nathans).
1972	Population screening for Tay-Sachs disease (Kaback and Zeiger).
1973	Prenatal diagnosis of neural tube defects by raised alpha fetoprotein (Brock). First Human Gene Mapping Workshop (Yale University).
1975	DNA hybridization (Southern) "Southern blot."
1977	Human beta-globin gene cloned.
1978	Prenatal diagnosis of sickle-cell disease through specific RFLP (Kan and Dozy). First mutation causing a human inherited disease characterized (beta-thalassemia). First birth following IVF (Steptoe and Edwards).
1979	Vogel and Motulsky's textbook <i>Human Genetics, Problems and Approaches</i> .
1980	Primary prevention of neural tube defects by preconceptional multivitamins (Smithells et al.). Detailed proposal for mapping the human genome (Botstein et al.).
1981	Human mitochondrial genome sequenced (Anderson et al.).
1982	Linkage of DNA markers on X chromosome to Duchenne muscular dystrophy (Murray et al.).
1983	First autosomal linkage using DNA markers for Huntington's disease (Gusella et al.).
1983	First general use of chorionic villus sampling in early prenatal diagnosis.
1984	DNA fingerprinting discovered (Jeffreys).
1985	Application of DNA markers in genetic prediction of Huntington's disease. First initiatives toward total sequencing of human genome (US Dept of Energy and Cold Spring Harbor meetings).
1986	PCR for amplifying short DNA sequences (Mullis).
1988	International Human Genome Organisation (HUGO) established. US congress funds HGP.
1989	Cystic fibrosis gene isolated. First use of preimplantation genetic diagnosis.
1990	First attempts at gene therapy in immunodeficiencies. Fluorescent in situ hybridization introduced to cytogenetic analysis.
1991	Discovery of unstable DNA and trinucleotide repeat expansion (fragile X).
1992	Isolation of <i>PKU</i> (phenylalanine hydroxylase) gene (Woo et al.). First complete map of human genome produced by French <i>Généthon</i> initiative (Weissenbach et al.).
1993	Huntington's disease gene and mutation identified. <i>BRCA 1</i> gene for hereditary breast-ovarian cancer identified.
1996	"Bermuda Agreement" giving immediate public access to all HGP data.
1997	First cloned animal (Dolly the sheep), Roslin Institute, Edinburgh.
1998	Total sequence of model organism <i>Caenorhabditis elegans</i> . Isolation of embryonic stem cells.
1999	Sequence of first human chromosome (22).
2000	"Draft sequence" of human genome announced jointly by International Human Genome Consortium and by Celera. Correction of defect in inherited immune deficiency (SCID) by gene therapy, (but subsequent development of leukemia).
2002	Discovery of microRNAs.
2003	Complete sequence of human genome achieved and published.
2005	Sequencing of chimpanzee genome.
2006	Prenatal detection of free fetal DNA in maternal blood clinically feasible.
2007	First genome-wide association studies giving robust findings for common multifactorial disorders.
2008	First specific individual human genomes sequenced.
2010	Sequencing of Neanderthal genome. Diagnostic use of human exome sequencing.
2011	Modern human genome shown to contain sequence from other ancient hominins (Neanderthal and Denisovan).

### Biography

**Peter Harper** was born in Barnstaple, UK; he trained in Medicine at Oxford University and in London, qualifying in 1964. After working at the Liverpool Institute of Medical Genetics with Cyril Clarke he spent 2 years as a research fellow with Victor McKusick at Johns Hopkins Hospital, Baltimore, before returning to Britain to found the Wales Institute of Medical Genetics at Cardiff where he became the Professor of Medical Genetics at the same institute. On retirement from this post in 2004, he was appointed as University Research Professor of Human Genetics at Cardiff University to develop his work on the history of human and medical genetics.

Dr Harper's main research interests have been in the clinical and molecular genetics of inherited neurological disorders, notably myotonic dystrophy and Huntington's disease. He has also been extensively involved with service delivery, policy issues and social and ethical aspects of medical genetics at a national and international level.

During the past decade he has led an international initiative to preserve and record the history of human and medical genetics; his historical books include *A Short History of Medical Genetics* (2008, revised edition 2013), *First Years of Human Chromosomes* (2006) and *Landmarks in Medical Genetics* (2004).

### 2.1 INTRODUCTION

The history of science is characterized by an exponential rate of expansion (1). No aspect has escaped, but biology, which is relatively new, has by all accounts exploded. Naturally, these changes are reflected in new principles, new thinking, and new ways of handling new information. Among the problems created is that of making these novelties available to practitioners of science of all kinds.

Among the ways suitable to medicine are massive volumes that contain detailed summaries of diseases, usually of one class, such as endocrine, gastroenterological, or, as in the case of *Principles and Practice of Medical Genetics* (PPMG), inherited. And of course, the pace of change requires revisions, always characterized by increases that reflect the rate of accumulation. Fission adds volumes whose pages, chapters, contributors, and diseases all do their best to obey the exponential imperative. Each chapter represents one topic more or less, an expansible topic capable of embracing new disorders with each new edition, so the number of chapters is no guide to the number of diseases. In addition to new diseases, new paths of basic science are added, a characteristic of books that mirror progress in reductionist investigation. But where is reductionist biology taking us? Clearly, one direction is toward fragmentation; more and more is learned about increasingly restricted fields so that even specialties bifurcate and medicine becomes ever more splintered. But despite such assaults, whatever it is we call medicine has at the bottom some integrity, some consistency, and common grounds that are clearly revealed in PPMG as well as in its sister enterprise, *The Metabolic and Molecular Basis of Inherited Disease* (MMBID) (2). One such common ground is genetics. And as there is included in both these books disorders of such a striking variety of cellular structures and metabolic mechanisms engaging every organ and organ system, it is easy to imagine that genetic variation is at the

basis of all diseases. This idea is far from new, having been suggested even in the eighteenth and nineteenth centuries, when it took the form of diathesis and idiosyncrasy (3). Then, in this century, it appears in the shape of a continuity between clear-cut segregating monogenic diseases and varying degrees of familial aggregation of cases that suggest the outcomes of the actions of more than one gene acting in environments favorable for the onset of a disease. But now, with the advent of genomics, which makes possible the study of the genetics of diseases of complex origin in families of patients who have affected relatives, as well as in those who do not, we are learning that genetic variation underlies the latter no less than the former. So the continuity of segregating to nonsegregating familial aggregation is extended to include cases where there is neither segregation nor aggregation (4). Perhaps we should require a disease to be shown not to be associated with any genetic variation, before saying it has no genetic basis.

All professions undergoing rapid change and increasing specialism face the same dilemma. The generalists who, as generalists, must keep up, find the density of new information daunting, even impossible to sort out and retain. So, books such as the PPMG are intended to present this information in an orderly way and in relation to specific diseases. But the job is no sooner done than even newer information arrives to change how the various disorders are perceived, and, of course, treated. Furthermore, new diseases have been described and must be included. Hence another edition must appear. And that's not all. The various sciences that contribute to our understanding are all changing, too, providing new insights that challenge conventional thinking. Editors respond to this intense pressure by including articles that present not only new information but also new insights, new ways of thinking about groups of diseases or perhaps all, and these usually appear at the beginning, hinting strongly that the reader of any later chapter would do well to read these preliminary ones.

It would seem that the editors of PPMG suppose that, for example, the principles of chromosomal organization, genomics or the investigations of diseases of complex

<sup>†</sup>Deceased.

origin would help the reader better to understand the chapters on developmental anomalies, the origins of high blood pressure, or inborn errors. And this may happen, given the effort. But each reader who makes this synthesis for himself or herself is likely to do it in the context of some specific disorder rather than to generalize the principles to all diseases. Indeed, we lack a clearly articulated set of principles of disease as opposed to diseases. That is not to say that medicine lacks principles; the idea of the body as a machine that breaks and needs fixing is one, and the medical history, diagnosis, pathogenesis, treatment, prognosis, and prevention all have a conceptual basis, as do the basic sciences related to medicine. But disease as a concept seems to be taken for granted. Textbooks of medicine, pediatrics, and pathology often begin with generalities, but not about disease. Medical texts sometimes begin by defining the practice of medicine, the meaning of signs and symptoms, doctor–patient relationships and medical ethics, whereas pediatric texts include growth and development, relations with parents, and the special quality of the medicine of infants and children. Perhaps it is an expression of medicine’s pragmatism. Why try to define something you know cannot be deciphered at a satisfactory level, even though you know that the level must be molecular? This is the view of the editors of the twenty-first edition of the *Cecil Textbook of Medicine*, published in 2000 (5). The editors say “true understanding of disease processes depends upon levels of scientific knowledge that are just being discovered.” Pathology probably comes nearest to touching on the principles of disease in generalizing on cell injury, inflammation, cell death, and tissue repair. But no book suggests that a student of medicine (and we are all students throughout the length of our careers) might take profit in an account of disease as opposed to diseases, including why we have it, who is likely to be affected and how, and when in the lifetime and what forms can it take, as well as what are its constraints? That is, what are the explanatory generalizations that compose a context within which to fit all diseases?

Similarly, definitions of disease have fallen by the wayside. It is true that many such definitions have been offered; there is a sizable literature on the subject (6–9). Perhaps today’s reluctance stems from physicians’ perception that we have not had the wherewithal for any but descriptions based on signs and symptoms rather than anything at its core. But today we are satisfied with a definition of a disease when pathogenesis is explained by reference to abnormality of some metabolic or homeostatic system, and we can describe the qualities of the proteins that compose the system. Now, if that is so, why may we not define disease as a consequence of incongruence of a metabolic or homeostatic system with conditions of life? And as all such systems are composed of proteins capable of reflecting the variations of their genetic origins, is it not appropriate to agree with Vogel and Motulsky who, in the third edition of their book, *Human Genetics*, proclaimed genetics as the principal “basic science for medicine” (10)?

If genetics is the basic science for medicine, it should be possible to construct a set of principles that characterize

disease in a genetic context. That is, a set of generalizations shared by all diseases and framed in genetic terms. And there should be hierarchies of principles, inclusive and of increasing generality and forming a matrix embracing them all. What follows is one such matrix.

## 2.2 THE PRINCIPLES OF DISEASE

A foundation for developing principles of disease exists in the ideas of Ernst Mayr (11). Mayr perceives biology as divided into two areas differing in concept and method. One, functional biology, is concerned with the operation and interaction of molecules, systems, and organisms. Causes are proximate, the viewpoint is inward, and questions are commonly preceded by how; how does the organism function? The other area, Mayr calls evolutionary. It is concerned with the history of functional biology, its causes are called ultimate, and its questions are prefaced by why; why in the sense of, what is the history of organisms, what are the conditions of the past that have made it possible to ask for answers to the how questions? The two areas of biology meet, or overlap, at the level of the DNA, so that the functional deals with everything after transcription, whereas the evolutionary centers on the history of the DNA as well as, presumably, with the evolution of the conditions of the environment within which organisms have attained their current state.

Mayr did not include disease in his description of the two biologies, but disease is no less biological than the ideal state, so there should be no difficulty in applying his principles to biological abnormality. So in relation to disease, the proximate causes are (1) the products of the variant genes and (2) the experiences of the environment with which they are incongruent. Ultimate or remote causes are (1) the mechanisms of mutation and the causes of fluctuations through time of the elements of the gene pool, including selection, mating systems, founder effects, and drift and (2) the means whereby cultures and social organization evolve. In disease, the variant gene products and the experiences of the environment with which they are incongruent account for characteristic signs and symptoms, but in making available the particular proximate causes assembled by chance in particular patients, it is the remote causes that impart the stamp of individuality to the case.

So the model relates disease to causes, to the gene pool and ultimately to biological evolution as well as to the evolution of cultures, and to individuality, the latter a consequence of the specificities of both causes. Here there are also elements for constructing a context of principles of disease, always remembering that the word context derives from the Latin word *contexere*, meaning to weave. That is, the principles must be seen to be related and interdependent so as to form a network of ideas within which to compose one’s thoughts about each specific example of each disease.

There is a further feature of Mayr’s views on biology, also crucial in its application to disease (12). It is the state of mind in which to observe patients. In medicine, we tend to think of patients in relation to their disease,

that is, as a class of people characterized by the name of the disease. This is what Mayr calls typological thinking. Although patients do differ somewhat from one another, they all share an essence: the disease. In contrast, Mayr proposes population thinking, in recognition that populations consist not of types but of unique individuals. So, in this context, disease has no essence; its variety is imparted by that of the unique individuals who experience it, each in their own private version, and the name of the disease is a convenience, an acknowledgment of the necessity to group patients for logistical purposes. The fruits of the Human Genome Project (HGP) can be accommodated only with such a populational perspective.

Why do we need such principles? Physicians are pragmatic; their way is determined by what they see before them, and students and especially residents are intolerant of anything they can label “philosophical.” But the principles are there, explaining the qualities and behaviors of diseases, and they await exposition.

But have we not already discovered them? Medicine is at the peak of success in diagnosis and treatment and moving rapidly to ever new heights of achievement. But all changes may not be equally evident. For example, the analysis of pathogenesis, traditionally a top-down process, is beginning to give way to a bottom-up approach in which discovery of variant genes leads to variant protein products and thence to the same molecular analysis of pathogenesis (see Chapter 16). Also, the genetic heterogeneity and individuality of disease are not easily accommodated in traditional thinking. So we are changing how we look at disease, how we define and classify it, and the language we use in describing it. For example, genomics and proteomics are new words that embody ways of thinking new in the past several decades (4,13,14). These developments are changing our relationships to biology and society. Biologists are expressing interest in the fates of the molecules they discover, and the public is becoming aware of what molecular biology and genetics mean to them, as risk factors, for example (15,16). So, because this same molecular genetics gives us new insights into the principles that govern—and have always governed—disease, should we not articulate those principles and weave them into our thinking?

Reasons for doing so lie in the need for coherence in medicine, coherence in the face of reductionist dispersion, coherence in bringing new developments to the whole of the medical enterprise and to the public, and coherence in medical education and the thinking that goes into it. No one can possibly know all the information there is, but we all need a context that can supply both a substrate on which to apply the new and a receptacle within which to encompass our own field. The principles of disease bear a relationship to diseases that resemble the relationship of military strategy to tactics, of historiography to the practice of history, or of grammar to precision in learning and speaking a language. Once such principles have sunk into the unconscious, they remain there as a context

and a basis from which the conscious thinking about the subject takes off. They are no longer “philosophy” but the basis for daily thought.

## 2.3 DEFINING DISEASE

If we are to define disease, it must be as loss of adaptation; the open system has had difficulty in maintaining homeostasis. So our question is how is this failure of adaptation attained? The straightforward answer is to say that a variation in a homeostatic system was incongruent with its environment, whether within the cell or outside, and the mechanisms for compensation were inadequate, momentarily or permanently, to restore congruence (see Chapter 16). As a result, other systems were affected, and then still others. But this only tells us that the machine broke down. If we would define disease, we must know what variations can lead to what levels of incongruence. We must know the weaknesses in the evolution of organisms, or if not weaknesses, the degrees of flexibility. That is, the origins of human disease lie in both human evolution and the environment with which the human species has evolved to be congruent. And because both biological and cultural evolution are continuous, although at markedly different rates, congruence must be relative and changing.

Such questions have always been germane to the definition of disease, however infrequently posed, but they assume a new relevance now because of the frequent assertion that one needs to know only the molecular form of the incongruence to devise an appropriate treatment. That is, all our problems could be solved at the molecular level. If this were true, we do not need to define disease except molecularly, and that is the vision we pursue. But before committing wholly to such a concept, it is as well to probe further into the question, what is disease?

It may seem odd to ask such a question; surely it has been answered again and again. And so it has, and many times, but always within the descriptive limits of the period. Descriptions and definitions of disease have in history proceeded from top down and from outside in. That is, from a history of the illness only, to history plus inspection, then on to physical examination in life and at autopsy, to increasingly intimate inspections by radiological and newer visual means, as well as biochemical examination, and now molecular analysis. Now that we can proceed from the bottom up, beginning with genes identified by genomics to their protein products and to the homeostatic systems into which they are integrated, the definition of disease should be reconsidered.

History reveals two opposing definitions. One, called essentialist, proposes that diseases exist somehow and in some way as entities that attack their victims. The other, called nominalist, is represented as a change within, an altered state, or a deviation in response to some stimulus. In the essentialist view, the patient is healthy and is brought low by the disease, whereas in the nominalist, the disease is an expression of the particularity of the

individual response to a stimulus. This modern-sounding construction was popular in the nineteenth century in the form of “diathesis,” in which there was suggested some element of heredity as well as individual vulnerability (3,17). It was swept aside by the essentialist version, which emerged, in the later part of the nineteenth and early twentieth centuries, when microorganisms were discovered. Then the nominalist began to regain favor as, first, biochemistry, then genetics, and then molecular biology flourished. Today, although we still experience microbial scourges, the nominalist view prevails, perhaps because we can so easily see that the responses to diseases, even to microbial assaults, are a product of the individuality of the systems of homeostasis and because we are more perceptive of the interrelationships of proximate and remote causes. But there is a lingering residuum of essentialism in molecular diagnosis, so often proclaimed to be a preliminary to some “designer” treatment, usually to be concocted by pharmaceutical companies who have made the word pharmacogenetics their own. Such a diagnosis is unobjectionable as far as it goes, but it has implications. That is, it is an essentialist view insofar as (1) it emphasizes the disease without differentiating the patient; (2) it includes only proximate causes, the gene and its product are perceived as no less essentialist than the microbe that attacks; and (3) it is typological. Even though allelic heterogeneity may be acknowledged, the variation is around the expressions of the “classical case.” There is no recognition that each patient will respond to the effects of the products of each gene individually, to say nothing of each designer drug. For many years, the monogenic diseases were regarded in an essentialist typological vein, but we have become more nominalist, more prone to population thinking, and more ready to recognize the significant effects of variability of both the genetic and the environmental settings in which the principal gene effect is measured (18). So, in defining disease, we must not only take into account the gene that seems most relevant to the phenotype—after which the phenotype may be neglected in the interest of molecular treatment—but also keep alive the relationships of genes (or better, of their products) and phenotypes, the better to grasp the individuality of each, so as to tailor the particularity of the molecular treatment to the biological individuality of a very particular patient. Then, having that principle in mind, the necessity to group patients for treatment can be managed rationally.

So, in the end, how shall we define disease? The elements of Mayr’s model must be satisfied. That is, the definition must include remote as well as proximate causes and the relationship of both to DNA. Also, it must be populational in concept rather than typological, which is to say, it must be nominalist. So, one way of expressing it is as follows: disease is a consequence of incongruence between genetically variable homeostatic systems and the kinds, intensities, and durations of exposures to elements of the environments to which they are called upon to adapt.

No doubt objections will be raised. Is cyanide poisoning a disease? No human variation is needed. Nor is there variation in susceptibility to scurvy, although it is unquestionably a disease. But although cyanide will extinguish all life, scurvy is a disease of species; only we and the guinea pig among mammals are vulnerable. Still, it is fair to say that human homeostasis is uniformly incongruent in the presence of cyanide and the absence of ascorbic acid, and so both qualify for this definition. Others see poisoning and trauma as something other than disease and call them by other names—accidents for one. But again the human constitution is incongruent with bullets and car crashes and so is vulnerable. How about infections? We have genetically determined mechanisms, both well developed and efficient, in coping with microbial invaders. Here, the variability includes individual vulnerability in the many immunodeficiencies, as well as individual invulnerability, both relative and absolute, in individuals who are immune to infections caused by many organisms including one malarial parasite, the tubercle bacillus, and the polio virus (19).

And if there are those that are immune to, who can doubt that there are individualities susceptible to particular organisms? In general, microorganisms attack at cellular sites we define as strengths but which they have defined for their purposes as our weaknesses; for example, cell surface molecules designed for high efficiency as elements of metabolism, but which the organisms have adapted themselves to use as means of access. The point is that it is usually variation in the microbial, rather than the human, cell that brings particularity to the encounter, although there may be both. So, because variation in either human victim or microbial attacker or both determine the nature of the encounter, infections fulfill the nominalist definition, even while as entities they are compatible with, and are even the prototype of, the essentialist definition. This suggests that both definitions are of historical interest only, suitable for the levels of description of disease that we have left behind. But they are still of value in showing how the more intimate we become with the human body, organ, and molecule, the more our concepts change and the more we need to shed old ideas and their locutions and adapt to what the new is telling us. But still we should observe that much of what is new was foreshadowed in the old. A leisurely reading of the chapter “The inborn factors in infective diseases” in Archibald Garrod’s book, *Inborn Factors in Disease*, published in 1931, underlines the validity of that observation (20).

## 2.4 THE HOW QUESTIONS

In the Mayr model, it is by way of DNA that remote causes leave their imprint on the proximate and it is the protein gene products that are the effectors of both. Once we spoke of gene–environment interactions, but now we know that the actual contact between these sources of variation is by way of those proteins. Indeed, one way

of perceiving the DNA is as a molecule that is helpless without proteins that carry out all its ends, including transcription and translation too (21). So the proteins carry on the life of the cell as elements in integrated systems, responding to influences from adjacent cells, distant organs, and the outside, to maintain the open system in its uncertain relationships in life. They are, therefore, unit steps of homeostasis, and as such are pivotal in concepts of life, development, aging, health, and disease.

Such a list of attainments is banal without explanation and illustration. In the following section, there are several ways in which the unit steps of homeostasis fulfill the purposes of the cell. They are called unit steps to convey their elemental state as units of pathways, and cascades, structural elements, protein machines, transducers in signaling systems, and transporters or receptors of molecules that are going somewhere. The phrase further implies units of integration into systems intended to maintain the organism's steady state; they are the node between nature and nurture, and the phrase has the virtue of being indifferent to whether or not the specific protein fulfills a useful purpose or is disruptive. And finally, the unit steps have an important historical meaning, representing the central idea of Garrod's inborn error, Beadle and Tatum's one gene-one peptide, and Pauling's molecular disease (22–24).

## 2.5.1 Some Qualities of the Unit Step of Homeostasis

**2.5.1.1 As a Unit of History.** Clearly, DNA is an instrument of memory, a memory that in preserving the past, gives guidance for the future. That is, the future must always reflect the past, and the means whereby this Janus vision is attained is the protein gene product that repeats its phylogenetic history in its current composition and function and predicts its future in its reincarnation through subsequent generations as itself or in the form of variants. Some of the variants have no future and their incongruence is noted by natural selection. Others are contingent, favorable for some conditions and inappropriate for others. And then there are those proteins that have hardly changed from microbial ancestry and that represent core functions. In human society, political and religious systems have similar capacities for endurance, revealing fundamental unchanged dogma associated with adaptation in ways that promote the cause with little change in the fundamentals. So the proteins that constitute our proteomes descend to us not only from our parents and other human antecedents but also, with variable conservation, from both the ancient and recent past.

**2.5.1.2 As Effectors of Gene Intention.** We often speak of a gene or genes as being “for” something, by which we indicate some sort of direct relationship to a phenotype. That is, we seem to be saying that the gene's influence is determining. And so it is, if by determining

we mean the sequences of bases in mRNA and of amino acids in a protein product. In this sense, the gene is indeed “for” something. But each gene product has in addition an emergent career of its own, not predicted at all, or only indirectly, by its gene. It assumes a position in the homeostatic device to which it belongs and can now be said to be “for” that system, as the factor VIII gene is “for” both the factor VIII protein and “for” clotting. But it is far from determining of clotting; all the other elements are needed, too, or, as we all well-know, life-threatening bleeding occurs. We also know that in physiology system is integrated with system in hierarchical relationships, so that the farther away from the steps of translation and first integration, the more dilute the gene's determining power becomes. No doubt the genes are involved wherever their products are to be found, but indirectly, and any one may have little power to shape the ultimate phenotype. In another sense, the genes appear to be hardly involved at all beyond transcription because it is the quality of the protein product that determines its role in the economy of the cell, a role that is determined by how the protein folds and takes shape, a shape that must accommodate to the shapes of the products of other genes and they with still others. No doubt the protein's folding and shape reflect the information residing in its parent gene, but its gene has no control over the shapes of those other proteins with which it fits, to say nothing of how multiprotein machines work (25). Here is a question not of genes but of how proteins interact. It is a matter of physiology. Indeed, it is possible that as the fruits of the HGP and the proteomists filter into medicine, we will hear a good deal less about genes and more about proteins (26). This could be less than ideal were the proteins not perceived to be as closely identified with the concept of variation as the genes. Let us see to it that they are.

**2.5.1.3 As a Unit of Development.** T. H. Morgan adopted *Drosophila* as an organism suitable for the study of development (27). But it did not work out that way, and his students led the way to the operational definition of the gene. So it is ironic that modern technology has made the fruit fly ideal for the very study that defied Morgan's efforts (28,29).

In development, the genes fulfill their intentions in the ways just described. Their products are the units of developmental change, assuming positions in systems appropriate for their conformation so as to give each organism a matrix, embodying a trajectory of change that is a product of how the embryo, fetus, and baby meet and respond to experiences of intrauterine and external environments. That is, development is a historical process; what the organism is today is built upon what it was yesterday and leads to what it will be tomorrow (30). And because the genes see to the continuity of their products throughout the changes of a lifetime, it is hardly likely that the influences of the past, however distant, would fail to influence the present. So if we would understand the origins and

expressions of disease, it must be in the context of three timescales, all at once: that of phylogeny, that of development maturation and aging, and that of the present (31). To know what we begin with is to know potential incongruence; to know where development is taking, or has taken, us is to clothe the potential with the probable, one way or the other; and to know where we are at the moment is to know the strengths and weaknesses that we will face tomorrow. There is an increasing interest in the idea that some diseases of middle life have precursors, manifestations dating to early, even intrauterine, life. These expressions may not appear to relate to the disease they are said to characterize. Rather, they may represent subtle changes in trajectories that, if pursued, emerge finally as disease (32). How else could birth weight be related to type II diabetes or heart attack?

**2.5.1.4 As a Unit of Individuality.** In medicine, patients are seen one at a time. Each one is biologically unique, has different experiences, and tells a different story. These expressions, together with the help of the laboratory and observations over time, are compared with those of the classical case to reach a diagnosis, and, allowing something for variation, treatment or management is devised. This thinking is typological, individuality is usually ignored, and the doctor is in thrall to nosology. The method works well enough, but heterogeneity of proximate cause may be overlooked and patients are likely to be aware when they are being perceived as representative of a class rather than as their unique selves. Now, molecular biology has given us the wherewithal to observe molecular individuality, that is, the capacity to make comparisons between individuals of variations in base pairs in the DNA and differences in amino acid sequences in proteins. The unit of individuality is the unit step of homeostasis, and the expression of uniqueness lies in how the variant proteins affect each its own system and the integrations of the latter with others, as well as how the systems respond to nongenetic proximate causes. Genomic analysis of single nucleotide polymorphisms (SNPs) suggests that the number of polymorphic loci expressed in amino acid substitution in proteins will turn out to be somewhat greater than the 30% we are accustomed to (33,34). This is the substrate of variability within which additional “private” variants as well as clearly bad mutants express their effects, and all this variation is manifested in how the integrated homeostatic devices are fulfilling their duties. So, if each human being is unique by virtue of the variant proteins in his or her whole physiological apparatus, why should not each such human being express an experience with disease as variously as a career of health.

Variation contributed by variant proteins is far from all. Such variability is compounded by the individuality of the developmental and maturational trajectory characteristic of each person, a path determined no less strongly by the kinds, intensities, and durations

of experiences than by the protein gene products with which they interact. But the final arbiter of individuality is the remote causes, which determine the specificity of both genes and experiences. The variation in the parental gene pool is a sample of what is available to the species, but it is necessarily limited, characterized by ethnicity and made local by founder effect, migration, and mating customs. These are all influences that determine the particularity of an individual’s genetic endowment. But if genetic individuality is both determined and constrained by the genetic raw material inherited at conception, so is the variety of experiences made possible and limited by the mores of the social and cultural milieu, itself often inherited, which shape our likes and dislikes, our indulgences and restraints, in short, the qualities and quantities of the experiences we encounter. So, in the end, it is the remote causes that confer the specificity of individuality, but the unit steps of homeostasis that supply the substrate. Of course, the idea of variant proteins as units of individuality is not a new one, having been proposed by Archibald Garrod as “chemical individuality” as early as 1902 (23).

**2.5.1.5 The Unit Steps as Effectors of Disease.** If the gene product is the implement of homeostasis, it follows that it is the effector of disease; certain of its variants are in some degree incongruent with the environment, inside the cell or out. That is, wherever the origins and mechanisms of pathogenesis have been laid bare, there are proteins at the root of it. How could it be otherwise, given that both structures and motivators of the functions of cells are proteins, and disease is a consequence of homeostatic incongruence. A critic might suggest infections as exceptions, but it is the congruence of the microorganism’s structures with our unit steps of homeostasis that allows them to attach themselves to cell surfaces and then to release toxin or to gain access to the cell’s interior and to reproduce there. It is they who define our strengths as weaknesses and our congruence as incongruence. And they do so by using the human gene products, the human unit steps of homeostasis.

The history of the realization of this role of the unit step in disease is of interest; it paralleled the successive descriptions and definitions of both genes and proteins (6). We all know that Archibald Garrod was the first to call attention to alkaptonuria as a hereditary alternative form of metabolism because of failure of an enzymatically catalyzed step (23). He called this, and other such metabolic aberrations, inborn errors to distinguish them from diseases. This was an insight of extraordinary penetration in which he recognized that the differences in protein composition that distinguished species must also differentiate individuals within species (35). But even by 1909 when his first book, *Inborn Errors of Metabolism*, was published, he could go no farther (17,35,36). Little was known about protein structure and nothing of sequence of amino acids, and it was not even established yet, to everyone’s satisfaction, that enzymes were proteins (37).

As for the gene in 1909, it was still defined statistically, and although phenotype and genotype were differentiated in that year, the gene was an unknown entity, perceived by Johannsen as “an accounting or calculating unit.” But by 1915 the gene had been defined operationally, so by then Garrod could have proposed the inborn errors as products of mutants of single genes. But he never did. Even in his 1931 book, *Inborn Factors in Disease*, he did not use the word gene despite a general recognition that genes were involved somehow in some diseases (20,35). For example, in 1927 Barker reported that, “No less than 223 heritable anomalies have been described in man already” (38). And others, not in medicine, recognized a biochemical relationship between genes and phenotypes: Wright in coat colors of guinea pigs and Wheldale in flower pigments (39,40). Then in the late 1930s and early 1940s, the studies of Ephrussi, Beadle, and Tatum, first in *Drosophila*, then in *Neurospora*, provided a functional definition of the gene that brought gene and protein unequivocally together to clarify Garrod’s observations, and capitalizing on rapid advances in biochemistry, to begin in the 1950s an era of biochemical genetics (22). Biochemical genetics was an ecumenical enterprise. If Garrod was its icon and Harry Harris its chief expositor, there were also contributions of nongeneticists, including Pauling’s concept of molecular disease and the elaboration of the enzyme deficiencies in (type I) glycogen storage disease, galactosemia and other disorders, all classical inborn errors, described by biochemists with no primary interest in genetics and who made no reference to Garrod or to Beadle–Tatum (24,41,42). But whatever the influence, the list of inborn errors expanded rapidly, soon attaining an exponential rate of increase that has never slackened.

It is worth noting that biochemical genetics flourished before the impact of the discovery of the double helix could be felt. But the later developments led first to Yanofsky’s definition of the structural gene with its correspondence to sequences in amino acids in proteins (43) and later to the definition of the gene that includes both transcribed and nontranscribed DNA. And this led, in turn, to the development of genomics as an analytical method. Thus biochemical genetics, whose analysis proceeds from the phenotype to the protein and its gene, met genomics, whose analysis proceeds from the gene toward the phenotype by way of its protein product (44). And in time, the glamor passed from biochemical genetics to genomics, perhaps principally because the former had no way to tackle the genetics of complex disorders. Actually both are needed because phenotypes are not necessarily explained on discovery of the gene or genes whose products are acting as proximate causes.

As the focal point in pathogenesis, the protein gene product provides an economical answer to the question of the origins of monogenic diseases. But the question of the moment is how to explain those called complex. The approach includes genomics, by which salient genes can

be found and characterized (14). Further steps involve discovery of their proteins and the homeostatic devices to which they belong, after which the pathophysiology may be elucidated. Additional participation by genetically inclined thinkers lies in sorting out the heterogeneity by means of appropriate family studies, work that must be done before, or together with, efforts to tie treatments to the consequences of particular protein variants.

Today we scoff at such diagnostic “entities” as dropsy and consumption, having begun long since to resolve their heterogeneity. But the HGP will provide the means to show how much more we have to go to characterize distinctive versions of, say, heart attack and stroke. So numerous are the genetic contributors likely to be that a case might be made for everyone having his or her own version of heart attack, stroke, or other multigenic multifactorial disorders. So family studies are vital for deciding which genes play important roles in which versions of the disease. The results will resemble those in the study of monogenic disorders; the heterogeneity will be of both loci and alleles, and the sets thereof will vary from family to family and individual to individual (18). This kind of genetic thinking, not yet routine in medicine, is crucial to our understanding and represents an important principle of disease.

**2.5.1.6 The Protein Product as a Unit of Selection.** Neodarwinism is the outcome of a debate in which geneticists agreed that the object of selection must be phenotype, not genes, whereas evolutionary biologists, to whom the phenotype had been that object all along, agreed that both phenotypes, and their variation, originated in the genes (45–47). If so, although the phenotype remains the unit of selection, it is the variable unit step or steps that cause it to qualify for that fate. In medicine, we are not much concerned with the selection by which species attain their characteristics but with what evolutionary biologists call “purifying” selection, that which removes “undesirable” genes prior to reproduction. So here again the protein product of the gene occupies a central position between two aspects of human biology. And here is yet another example of the cleavage between biology and medicine. The irony in the word purifying is not lost on the physician to whom the protection of life is uppermost, while to biology, with no stake in the individual, the question is purely one of understanding the rise and decline of species. But, in fact, variations in unit steps of homeostasis are no less the stuff of positive selection than negative.

**2.5.1.7 As a Hedge against Genetic Determinism.** Institutions change and renew themselves but they always retain residual signs of their origins. No one would deny that all the genetics of today stems from the concepts elaborated in the fly room at Columbia, or that we continue to use both concepts and language appropriate to the drosophilists’ definition of the gene (21). Theirs was an operational definition in which authority for both heredity and cellular function was accorded to

the gene. In his book, *What is Life*, Schroedinger spoke of the gene as “law code and executive power” as well as “architect’s plan and builder’s craft in one” (48). So the language of *Drosophila* genetics included such locutions as genes “for” gene–environment interaction, modifiers, penetrance, and pleiotropy, all of which are perceived as properties of the gene, although we know now that they refer to events mediated by the protein unit steps of homeostasis. There is no question of the latter’s specification by the genes, but in folding and assuming an appropriate position in a relevant homeostatic device, they become a part of mechanisms that regulate both themselves and the DNA (see Chapter 16). Thus it is not the genes that are penetrant, pleiotropic, or that interact with the environment, it is the proteins that do these actions that are removed from the genes’ control.

It might be correct to speak of a “gene for” say an enzyme or even its pathway; for example, there is a “gene for” phenylalanine hydroxylase and “for” phenylalanine degradation. But in their further integration, proteins lose their identity in those of integrated functions, for which any single gene can no longer be perceived to have any authority.

There is another way in which the locution “gene for” is used. When we observe that a disease segregates, we say there is a “gene for” that disease, that one or more mutants act as proximate cause. That is exactly what the drosophilists did for their mutants, unconcerned with their ignorance of how a gene could shorten bristles or deform wings. We continue to use their discourse, even though we know that the protein product is the actual agent of function (21). But “genes for” is a tricky phrase. When we use it unthinkingly, as in genes for high blood pressure, say, we obscure our own inner view of the reality, whereas when we speak of variant proteins, there springs immediately to mind pathways, cascades, receptors, transducers, and feedback loops (see Chapters 16, BP). Incidentally, it is amusing to imagine that had Archibald Garrod come to alkaptonuria thinking like a geneticist of the time, he would probably have perceived it only as a recessive character, not an inborn error. But he came to it as a biochemist and saw it for what it was: a metabolic alternative due to the absence of an enzyme. He used the genetic evidence expressed in consanguinity to support the idea of heredity, not as evidence of a gene. So, rather than perceiving his lack of interest in genetics as a shortcoming, we should be glad of it because the idea of a “gene for” alkaptonuria could have stood in the way of his biochemical insights. But equally, had he pondered the work of the drosophilists emerging in print from 1905 to 1920, and which included their operational definition of the gene, the second edition of his *Inborn Errors of Metabolism* published in 1926 must surely have anticipated the Beadle–Tatum one gene–one enzyme principle (49).

So, if we human geneticists of today revert occasionally to the drosophiline mentality, how likely are patients, their families, and the public to escape? How are they to

know that the words “gene for,” say IQ, artistic ability, or criminal behavior obscure the unfathomable complexity of the identity and actions of gene products integrated in hierarchies to compose cells, organs, and whole organisms, all in touch with one another and with the outside? The extremes to which “genes for” can go are summarized in a book called *The DNA Mystique: The Gene as a Cultural Icon* by Nelkin and Lindee (50). But fortunately we have our mental image of the products of the genes, the unit steps of homeostasis, with their multifarious behaviors as a bulwark against loose thinking.

**2.5.1.8 As the Goal of HGP.** One road to the discovery of new principles of disease is the HGP (51). Lander has suggested that this bears the same relationship to biology that the periodic table bears to chemistry (14). So it compels our attention. Furthermore, it is the ultimate identifier of those homeostatic units that lie at the basis of pathogenesis.

About 20,000 or so genes and their products have been identified, and sooner or later, the products’ roles in homeostasis will follow, with obvious benefits for investigation of pathogenesis, treatment, and prevention. In addition, definitive samples of gene products, useful in defining disease, will be available for characterizing human biological properties hitherto unknown. A few examples of questions that are being asked are

1. How variable is the human genome? Is it more, or less, than the estimates of Harris and Lewontin? Studies of SNPs suggest more as do the results of the Thousand Genomes Project (33,34). Nothing could be more useful than this answer because it is the common genes that so often act as modifiers and furnish the wherewithal for complex diseases.
2. Is there an inborn error for every locus? And are all classes of proteins equally involved in diseases? In a comparison of 348 mutant proteins associated with inborn errors listed in MMBID, seventh edition, and a list of 3000 “core” proteins shared by yeast and *Caenorhabditis elegans*, the distribution of protein types in the two samples was remarkably similar (52). Although indirect, the suggestion is there that all protein types are involved in inborn errors, but we cannot yet say that there is an inborn error for every locus, however plausible the idea may be.
3. Are diseases characterized by the qualities of the proteins that are their proximate causes? For example, do enzyme deficiencies differ in some systematic way from disorders associated with receptors, transcription factors, or structural proteins?
4. Are conserved genes over- or underrepresented in disease? One might expect them to be overrepresented on the assumption that they fulfill critical functions or underrepresented because their mutants might be so often lethal.
5. What is the role, if any, of developmental constraints in fostering or suppressing disease? These are limitations on the evolution of phenotypic variation

expressed in developmental blind alleys. Kirschner and Gerhart have examined ways by which such constraints are loosened to allow new mutation and evolutionary progress. But would some of the latter be disease (53)? And Rutherford showed how, in *Drosophila*, such constraint was exerted by a heat shock protein (54). When altered by mutation, the constraining force was lifted and the effects of mutants suppressed by the wild-type protein were observed. Some of these effects were developmental anomalies.

6. Are diseases characterized by the evolutionary age of the proteins that lie at their root? That is, we might suppose that inborn errors of housekeeping genes shared by remotely related species were the oldest. Do they differ in any particular from diseases of the most recent mammalian or human genes?
7. What are the implications for aging? Are some proteins more frequently the object of aging processes, or is it random? Errors in the mitotic machinery that led to multiple abnormalities of regulation of dozens of enzymes increase with age (55). So, will aging, which has been perceived by some as dishomeostasis, turn out to have the same molecular basis as disease?

Many other questions are being asked, many no doubt not now askable because the contexts in which they are relevant are unknown. As more and more diseases are given molecular definition, we will surely classify them differently, departing from the current anatomical, organ system, age-related rubrics, moving to more molecular designations. As heterogeneity is laid bare, old classes will go and new ones will come, reflecting a sharp revision in how we will see disease itself. In addition, our language will change. It is likely that we will refer less to genes and more to proteins, so our residual *drosophiline* language is likely to go, too. Of what use are words such as modifier, epistasis, penetrance, pleiotropy, and the like when visualizing the reality as actions and interactions of proteins, in say, multiunit machines, or even in whole systems (14)? This also suggests that we in medicine will be thinking less in units and more in multiunit devices (proteomes, metabolomes, etc.). Linear thinking may be out as complexity moves in. But maybe the most significant change in our thinking will be compelled by the definitive evidence of human variation and individuality. Typological thinking will give way to population thinking. No doubt there will always be use for the former at one level; that of the value of means and the classical case, but only as a preliminary to the population thinking that perceives the extent and impact of variation on human individuality.

**2.5.1.9 Social Impact.** The unit step of homeostasis is attaining increasing prominence as a risk factor and signal for preventive action, and medicine has been adapting not only to their potential use but also to their impact on their possessors' lives. These concerns are well-known to readers of PPMG; they have been the subject of many

papers, books, and committee reports and they touch on counseling, ethics, legal matters, and psychological impact (15,16,56–58). They are mentioned here because of the potential uses of such risk factors in prevention. If the HGP fulfills its promise, there is the possibility to know the protein products of all genes known to participate in pathogenesis. Many scenarios as to the use of these markers have been offered. Only time will tell which, if any, is practical, but we would be wise to continue our study and preparation. How to use information, available at birth, about many variant genes, perhaps dozens in single individuals, and known to be associated with diseases all across the life span is something entirely new in medicine. Is it consonant with good medicine? Is it acceptable to the public? How do we prepare the public to make rational decisions about it? How do we prepare individuals to accept and use constructively such emotionally loaded information? These questions can be answered only in colloquy with the public.

**2.5.1.10 As a Source of Coherence.** In concentrating on the specificities of the pathogenesis of each disease, reductionist investigation emphasizes the separateness of diseases. It exerts a centrifugal effect that adds to that of our conventional nosology, which divides medicine into specialties across which we interact collaboratively, when at all. But the concept of the unit step of homeostasis as the central focus of all pathogenesis provides a principle of disease that exerts a contrary centripetal force that unifies the thinking about both disease and diseases. It is the difference between analysis and synthesis. Medical thinking, until recently, was mainly synthetic. It dealt with the body as a whole, no doubt because of ignorance of its parts. In contrast, in the thinking of today, the emphasis is on analysis; our attention is directed more to microunitary parts with less attention to the whole. But in acting as units of the mechanisms whereby an open system maintains its adaptation to an indifferent environment, the protein gene product is the effective link between those proximate and remote causes portrayed in the Mayr model. And that link is no less evident when unit step and environment are incongruent than when congruent. In the Mayr model, the proximate causes are consequent on the DNA and pose questions prefaced by how, whereas the remote causes lead up to the DNA and pose questions prefaced by why. In this summary of the role of the protein gene product, we have dealt with how questions. In the next section, we examine the why questions and the principles they illustrate.

## 2.6 THE WHY QUESTIONS

Just as the questions preceded by “how” are answered by reference to proximate causes, so are the “why” questions answered by reference to remote causes. And the answers to the why questions contribute no less to the specificity of identity than the proximate. Indeed, they are the enablers, the ultimate arbiters of that specificity. So we are what we are by virtue of endowment, experience, development,

maturation, and aging, but the bounds of what we can be and the precise description of what we are, are determined by how the remote causes came to be what they are and how they were sampled in the making of the individual. So the answers to the why questions are likely to probe more widely and deeply than those preceded by “how.” In fact, they begin with the latter to give them specificity. And yet we spend most of our energies and money on seeking proximate causes. The imperatives of treatment and prevention require it, yet it should be observed that it is the “why” questions that are most often asked by the public, particularly by those affected by disease. Medical education would do well to include them.

### 2.6.1 Why do we have Disease?

Why is it that after all these eons of evolution, species have not evolved to perfect attunement with the environment? First, it must be said that we are remarkably well adapted. Increasing longevity suggests that in the developed world we are moving toward the ideal rectangular survival curve (59). That is, we are moving in the direction, at least, of some probably unattainable minimal amount of disease compatible with some necessary degree of genetic diversity. In addition, the environment changes, requiring new adaptation, and then observation suggests that nature never reaches for perfection but for some compromise that ensures perpetuation of species usually at the expense of individuals. For example, the fecundity of our own species is presumed to be of the order of only 25%, and not all of that makes it to maturity (60). But that a principal hazard to the global ecology is a surplus of human beings is testimony to nature’s way of doing business.

Because evolution proceeds by the intervention of natural selection, there must be something to select, and again, although there are mechanisms of astonishing precision to ensure the accuracy of replication of DNA, they are not perfect either, and so, after the removal of individuals unlikely ever to survive or reproduce, we are still left with sufficient variation among individuals to adapt to the randomness of change in the environment. This includes genes that are either neutral under all conditions or contingent, that is, adaptive under some conditions but nonadaptive and conducive to incongruence and disease under others. So disease must be presumed to be a by-product of the necessity to have enough variability for all conditions.

### 2.6.2 Why this Disease?

Patients often ask this question. “Why,” they ask, “should I have diabetes or cancer?” or “Why should my baby have this bizarre disease I’ve never even heard of?” The media have spread the news of genetics, so their question may be, “Is it in my genes, and if so where in the world did such genes come from?” So the questions are directed to both proximate and remote causes. First

to the proximate, which include the genetic endowment received by the patient at conception and which, together with the kinds, duration, and intensities of experiences of the environment, have created a developmental and maturational matrix that is an expression of individual potential from day to day. Then, the parental contribution to this matrix reflects the specificity of their genes, themselves representative of one or more gene pools, each with its own variable composition and history. The contributions of experiences are representative of qualities of the society the patient inhabits, qualities that vary with cultural history. And finally, the contribution of development and maturation is that of a trajectory whose specificity is derived from both endowment and experiences as they create and characterize the evolving matrix within which the incongruence and disease are engendered. So the answer to the question of “why this disease” requires us to acknowledge that while the disease is a consequence of incongruence between proximate causes, it is the remote causes that account for the existence, availability, and particularity of those proximate factors.

### 2.6.3 Why this Person?

If patients are baffled by the disease they experience, they are angered by its apparent choice of themselves. “Why me?” is their injured cry. Of course, the reasons reside in the origins and specificities of genes, experiences, and development given in answer to the previous question, but “Why me?” is a profoundly different question because, no matter how specific the genes, the experiences, and the development, so long as it is only the disease itself that commands our attention, there is the possibility that we miss the full impact of the individuality of the patient, its multifariousness, its history, and its uniqueness. There is always a healthy side to a sick patient with its own proximate and remote causes and its diversity. And it is in noting those qualities that some clinicians are distinguished from others to whom the particularity of the patient lies only in his or her variant molecules. In fact, it is in appealing to the particularity of the whole patient, molecules included, that the physician is able to help the patient to discover and to mobilize resources that may make the difference between a timely and a delayed recovery, or even between life and death.

### 2.6.4 Why at this Time?

Perhaps the least understood by its victims is disease’s apparent caprice in choosing when it strikes: the infant, blooming and full of promise, who wilts and dies; the robust, active college student who dies in one or two days of meningococcal meningitis; the busy, tireless 50-year-old who is felled by cancer. No doubt in old age disease and death are less anomalous, more expected, and yet we must ask why one person is privileged to die at 90 years, whereas others have died untimely. But we know that

there are reasons for ages at onset of diseases and that they are accommodated within the nominalist definition of disease. These reasons are embodied in human mortality curves that, in the developed world, are U-shaped, declining sharply after birth, reaching a nadir at adolescence, and beginning to rise again in young adult life. If we were to include life before birth, the postnatal decline would be seen to be the end of a steep drop through intrauterine life.

Table 2-1 lists and contrasts qualities of the diseases experienced on the two sides of the U. How do we explain the differences? Again, appeal to remote causes gives the answers. All differences are those expected if the heritability of disease were to fall throughout life. The table tells us that indeed it does decline; the incidence of monogenic disease drops sharply before the nadir of the U, which suggests strong selection against disorders that imperil reproduction, leaving postpubertal disease to be

associated mainly with the kind of genetic variation that is contingent, implicated in disease only in the presence of nongenetic proximate cause, and representative of the kind of variation successful species exhibit. But, although the distribution of mortalities is U-shaped, the principle of continuity is not defied; monogenic disease continues to occur even in late life, and diseases of complex origin are known in childhood, even in utero (Figure 2-1).

Another way of perceiving in more detail the decline in prominence of the genetic impulse in disease is to express it as a decline in a gradient of selective effect. The gradient is not of genes but of phenotypes, and the weight of selection is heaviest in utero and least in old age. Burden is measured in risk to life, curtailment of reproduction, and permanent disability. These are biological burdens such that loss of life in utero, even before implantation, is more burdensome than the death of a bread-winning parent at age of 40 years with all its social upheaval. The apparent discrepancy in these burdens is a consequence of a natural ambiguity in human life in which we have two selves: one biological and the other social. It is as if we live two lives, one in obedience to the biological imperative to survive to reproduce and the other to exploit endowment and opportunity to have a fulfilling social life. Obviously these lives are intertwined, but when in opposition, there is a schism that may lead to disease.

The gradient is at its peak in utero where for reasons we can only guess, the majority of conceptuses are found wanting and die. Because intrauterine life is protected from the outside, most of this mayhem is likely to be genetic; for example, known early losses are most frequently associated with chromosomal anomalies (60). But there must be inborn errors as well, involving among others, proteins specific to development. Then there are many known inborn errors with onset early in postnatal life and constituting a significant proportion of disease in newborns. In keeping with the biological desirability of a population of reproducers

TABLE 2-1	Differences in Pre- and Postpubertal Diseases	
	Prepubertal	Postpubertal
Mode of inheritance	Monogenic	Multifactorial
Age at onset	Early	Late
Frequency	Rare	Frequent
Latency	Short	Long
Affected relatives	Numerous	Few
Diagnostic specificity	High	Low
Number of diseases	Very many	Fewer
Burden	Great	Less
Sex differences	Occasional	Frequent
Influence of migration	No	Yes
Secular change	No	Yes
Effects of SES	Some	More
Success in treatment	Some	More
Heritability	High	Low
Predictability	High	Low

SES, socioeconomic status.

FIGURE 2-1 Continuity of disease across the lifetime.

unencumbered by such mutants, 90% of single-gene diseases will have been disclosed by puberty and 99% by the end of reproduction (61). As teenage passes into early adult life and that into midlife, the residual monogenic disease consists mainly of the cases of earliest onset of complex diseases, the most severe, life-threatening and resistant to treatment, whereas those with later onset, milder, more responsive to treatment are of complex origin, often irregularly familial or sporadic, a continuity commensurate with a high degree of heterogeneity of proximate cause. At the lowest end of the gradient are degrees of health expressed in resistance, completing the continuity that began with the mayhem in utero. Resistance to disease is little noticed in medicine where appeals to the doctor are only made when the patient is sick, but it is well-known in infections.

In keeping with the concept of declining heritability, we expect an increasing contribution of nongenetic variation. Most cancer takes its origin from mutation, but it is mainly somatic and so may be counted as of environmental origin, perhaps as an aspect of aging. Aging is perceived as dishomeostasis, a product of cell loss and dysfunction due to denaturation of proteins. So while gerontologists, no doubt correctly, decline to see aging as disease, its expressions are associated with failure of the same gene products we associate with disease.

The decline in heritability is not monotonic but rises and falls according to developmental phase (see Figure 2-1) (61). For example, the genetically determined intra-uterine disease has an early onset, whereas fetal disease late in pregnancy is more likely to be of maternal origin; prematurity, placenta previa, hypertension, premature placental detachment, and the like. Then there is a fresh spate of genetic disease in infancy, with deaths in childhood being more likely to be due to poisons, infections, accidents, and in some places, homicide. In adult life, early-onset cases of complex disorders are strongly conditioned by genetic variation, whereas late-onset cases are likely to be nonfamilial (62).

Reasons for this phenomenon are conjectural, but it makes sense if the effects of new sets of genes are exposed to selection at the beginning of each developmental phase. It is an observation that needs study. Another kind of continuity exhibited by the gradient of selective effect is the overlap of disorders characteristic of different developmental phases (see Figure 2-1). For example, most chromosomal anomalies are lethal in utero, but for some there is a backwash of live-born babies. But not all malformations are due to chromosomal aberration; some are of complex origin and some are harmless and may be recognized only at autopsy or emerge only under conditions of unusual stress, such as urinary tract infection in a patient with a single kidney, perhaps in adult life. Prepubertal life is characterized by monogenic disease, but type I diabetes, asthma, inflammatory bowel disease, and other disorders of complex origin sometimes have onset then too. When a disease has onset over a broad range of ages, we must always wonder whether all victims to

whose disorder we give the same name actually have the same disease. So in complex disorders, the problem of naming will be with us until we are able to sort out the heterogeneity. In the end, it seems likely that the number of diseases of adult life will be no less than those of the prepubertal years. No doubt genomics will identify the genes, and the issue of names will be resolved.

One reason why this description of the decline in heritability, with its stops and starts and overlaps, has been given prominence here is to illustrate the principle of the continuity of life, a continuity often ignored in both concept and organization. Hospitals, medical schools, and medical education are arranged around age and organ system for perfectly good reasons, and the system has proved its worth. But molecular genetics provides a continuity that brings the specialties together in taking a longitudinal view of human life.

## 2.7 PREVENTION AND TREATMENT

One might suppose a priori that the Mayr model could not accommodate prevention and treatment of human disease. Biology is concerned with what is and does not accommodate intervention; the minute one intervenes, what is no longer is. And what could be more unnatural than government agencies that regulate how we deal with nature, or surgical transplantation of organs as a treatment, to say nothing of the idea of designer drugs for molecular defects. But we cannot escape our biological heritage, nor do we wish to, so perhaps the model is apposite after all.

All organisms are capable of adapting to, or otherwise defending themselves against, uncongenial environments. Some call upon homeostatic flexibility when under stress, whereas others move to evade it; evolution has seen to these self-protective capabilities. For example, many organisms have molecular mechanisms to withstand stress; heat shock proteins are one (63). Others are enzymes that detoxify foreign substances, and a third is up- and down-regulation of metabolic systems. Some organisms remove themselves from threats. In addition, animals that can, choose surroundings appropriate for their physiology and improve them too (64). So, in the sense that they know what experiences to avoid, animals practice prevention, and when attacked by disease or hurt in the course of the day's work, they fall back on natural mechanisms by way of treatment. The difference between them and us is that we consciously intervene in both. But in the degree to which we seek out proximate causes intending to alter them by prevention or treatment, and in the degree to which we try consciously to influence social and cultural conditions with an eye to changing remote causes, we do fulfill the expectation of the model.

### 2.7.1 Prevention

Constituted separately from medicine and described as improvement in diet, housing, and other living

conditions, prevention has saved more lives than treatment (65). And when microorganisms were identified as proximate causes, they became the target of prevention by quarantine and immunization; the latter remains a staple of medical care. These preventive measures were and are in the hands mainly of local government, whereas progress in fostering the ideas and promoting education in preventive medicine were and are the work of university-based schools of public health and hygiene. After the 1950s, when antibiotics reduced the mortality of infections, other diseases such as diabetes, cancer, and kidney disorders came into focus. Then the ideas of preventive medicine and epidemiology, which had been restricted to the control of infectious diseases in populations, began to include prevention of noninfectious disease in individuals, leading to the establishment of organizations that included patients, their families, and the public, and that were devoted to education and counseling of patients and relatives as well as the general public with the intention to prevent and to learn enough to treat these common disorders. The American Cancer Society, the American Diabetes Society, and The March of Dimes come readily to mind. In the 1960s and 1970s as more and more inborn errors were described, this principle was also applied to the generation of a multitude of disease-related societies, each dedicated to education, treatment, and prevention of one disease, the latter in the form of reproductive counseling, antenatal diagnosis, and sometimes abortion. Then, as the molecular basis of these disorders was discovered, newborn screening for inborn errors was offered by many state health departments and intensive studies were undertaken of every aspect of this form of preventive medicine including screening, counseling, and issues both ethical and legal (56,66–70). The question then arose of testing relatives of patients with inborn errors with an eye to reproductive advice, and the triumph of Tay–Sachs testing is one result (15,56). And now that rapid progress is being made in unraveling the genomics and proteomics of complex disease, time will give us more risk factors in the way of variant genes and proteins. These developments are reviewed here in this detail to call attention to the movement of the focus of prevention away from populations to individuals, and now to the molecular emphasis in both prevention and treatment. Just as the discovery of genes associated with disease suggests the possibility of cure, so does it suggest prevention by testing of relatives and populations. Indeed, the logic of prevention is even more powerful than that of cure. That is, unlike treatment, which is always after the fact and is occasionally as threatening as the disease it is designed to combat, prevention spares the organism such rigors even while far less disruptive of social and economic life. On the other hand, in keeping with the principle of continuity, the two are sometimes indistinguishable.

So, may we expect miracles of prevention now that we can identify proximate causes? Readers of PPMG

know that we may not (15,16,57,58). It is a matter of the continuity of the gradient of selective effect. At one end, the virtual elimination of Tay–Sachs disease among Jews and the prevention of a few other inborn errors by the same means represent successes of the high technology promoted by Lewis Thomas (71). At the other end are healthy centenarians who attribute their robust health to some idiosyncratic behavior. But in between are those genes and their variant products whose virtues are a sometime thing, depending on, on the one hand, the specificities of experiences over the lifetime, and on the other, their support, or reinforcement in failure, by the variant products of other genes. So the same variant gene product may be adequate in one person and fail in another even in the same family. Or it may be within the same person adequate under one circumstance and insufficient under another. Thus, as a predictor, a gene may be of only limited use to an individual even while accepted as a significant risk in a population. This is a frequent problem of epidemiologically designated risk factors; it is not always clear to whom among their possessors the trait is actually risky—to say nothing of gradations in risk. It is the problem also of evidence-based medicine, which, however valuable in increasing the rigor of diagnosis and treatment provides recommendations suitable for populations, not individuals (72–74). It is a matter of typological, as opposed to population, thinking. Of course, the HGP has added greatly to the list of our genes and their proteins so that the exact identity of all of the units in pathways and other homeostatic devices will be known, improving thereby the predictive value of various combinations of variants (75). And, assuming increasing identification of exterior proximate causes, the accuracy and usefulness of preventive predictions may improve remarkably. The necessity for the advancement of knowledge of nongenetic proximate causes cannot be exaggerated. We need a project of similar scope and ambition to that of the HGP. In the meantime, we should do what we can where we can, and for the rest, fall back on an aspect of medicine that may have become unfashionable in modern times but which is perhaps more than ever needed: helping patients to live with uncertainty.

A far less likely, but more effective, means of health promotion is the control of remote causes. The virtue of such an approach is clearly indicated in the Mayr model wherein the relationship of the two kinds of causes and the two kinds of biology is so lucidly stated. To influence by law the distributions of genes is both unconstitutional and in strong opposition to “liberty and the pursuit of happiness,” but to influence the organization of society and culture for the betterment of health is not only possible but also already the aim of numerous government agencies, the even more numerous private disease-related societies, as well as physicians who have advised their patients to practice healthy ways. But what has not been emphasized, at least in the United States, is the power of corporate action, of putting the weight of the whole

medical profession socially and politically on the side of health promotion. Today in the United States this is impossible, and some will say it is undesirable, but the point to be made here is the logic of the position. On one side is the power of remote causes in the origin of disease (let us think here of the evolution, growth, organization, penetration, and political powers of the tobacco industry) and on the other is the power of societies to organize themselves to influence those remote causes. In the United States, it was public opinion followed by legal action that began the descent of the authority of tobacco. There are other social conditions likely to retard the advance of prevention. One of these is the combination in the public mind of a superficial grasp of progress in biology and genetics and an unreasoning belief in the limitless potential of that progress. But for a recipient to respond realistically to the offer of prevention requires the ability (1) to differentiate between personal and populational probabilities, (2) to grasp its potential for success or failure, and (3) to participate constructively with a knowledgeable and sympathetic physician in greeting either success or failure. We do not often think of the evolution of education, or of the public grasp and acceptance of advances in medicine as remote causes of success or failure, but we should.

### 2.7.2 Treatment

The essence of Lewis Thomas' concept of high technology in treatment lay in the discovery of the exact point or points in the machine that were broken and that could be repaired by a single, simple, straightforward maneuver (71). One of his examples of such a treatment was the use of steroid in the adrenogenital syndrome. And after the 1950s, amid the rapid accumulation of newly described inborn errors, there was optimism that such diseases would be brought under control (76). But results so far have been something less. In the 1980s, Hayes tabulated successes and failures in 65 inborn errors, a part of a larger randomized sample of monogenic diseases taken from MIM 5 (77). Table 2-2 shows that for 12%, treatments were successful in rendering the patient normal or essentially so, whereas in 40% there was some improvement, often not very impressive, and about 48% showed no success at all. A further examination of success or failure in treatment of the same 65 diseases 10 years later was reported by Treacy with results shown in Table 2-2 (78). There was no increase in the number of very successful treatments, but some of the previously resistant disorders now yielded in some degree, often to such rigorous therapies as tissue and organ transplantation. These, Thomas saw as middle technologies, sometimes effective, but expensive and perhaps hard on the patient. A third look in 1999, this time including 517 inborn errors listed in the seventh edition of MMBID, gave much the same results (see Table 2-2) (79).

**TABLE 2-2 Effectiveness of Treatment of Inborn Errors**

	1983 Hayes	1993 Treacy	2000 Treacy
Fully beneficial	12 <sup>a</sup>	12	12
Partially beneficial	40	57	54
No benefit	48	31	34

<sup>a</sup>Percentage of total.

Given the qualities of the inborn errors that were the object of treatments, the record is perhaps not surprising. Most are at or near the top of the gradient of selective effect, some are lethal, and some are permanently crippling. And all are heterogeneous, some as to loci, all as to alleles. And we now know that we must expect equal heterogeneity among those shadowy modifiers we presume to exist (18). So these disorders are simply the most intractable. But farther down the gradient, the diseases are more amenable, not necessarily to cure, but certainly to management. This seems to be telling us that there is a relationship between heritability and success in therapy. When the heritability is high in a population, we expect less of treatment than when it is low (i.e. fewer patients are likely to respond satisfactorily). The history of treatment of rickets with vitamin D is exemplary. When, after the mid-1940s rickets almost disappeared, nearly all that was left were several different kinds of monogenic vitamin D-resistant rickets (20). This experience seems to furnish medicine, especially preventive medicine, an aim, even a motto. We work to drive the heritability of disease toward 1.0. And we fervently hope that the gene therapists will confound the motto by inventing high-technology treatments that subdue even the most "genetic" and even the most refractory of those disorders that continue to resist every effort to contain them. As for the complex disorders, they are resistant, too, but in a different way. If every individual has his or her own set of proximate causes, the complexity is of a high degree. The problem is one of discovery of the nongenetic causes and trying to eliminate them, as well as discovering which sets of genetic causes pose vulnerability to the threats of those nongenetic influences, both in general and in each affected individual. No easy job, but we are up against a wily opponent. Many years ago, Max Delbrück observed that "any living cell carries with it the experiences of a billion years of experimentation by its ancestors. You cannot expect to explain so wise an old bird in a few simple words" (80). We are definitely embarked on an effort to expose that wisdom. The next two or three editions of PPMG should show how wise the old bird is.

## 2.8 CONCLUSION

The explanatory principles of disease begin with the capacity of the species for genetic variability, a capacity

that is required for survival of species and that is experienced randomly resulting in genes whose products have, through time, conferred upon their recipients a status of congruence with equally variable environments. But sometimes the result is incongruence, which can lead to disease. It is in the gene products, the protein unit steps of homeostasis, that this species variability is expressed in congruence or incongruence in health or disease. This expression occurs within a biochemical and molecular cellular matrix conditioned by interaction between such protein products and experiences of the environment through development, maturation, and aging. Accordingly, analysis of pathogenesis must be pursued in three timescales all at once: that of phylogeny whence the genes and their products were derived; that of ontogeny, maturation and aging, which condition the ever-changing matrix; and that of the moment representing the impact of today's events. This principle, embracing the three timescales, also incorporates two kinds of causes, proximate and remote, which are expressed in the uniqueness of individuals. The incongruent proximate causes, variable protein unit steps of homeostasis and varying kinds, amounts and durations of experiences of the environment, account for the expressions of disease phenotypes that are subjected to selection and incur the social stigmas that complicate the lives of their victims. Remote causes are composed of the evolution and dynamics of both biological and social milieux that account for the nature and local availability of proximate causes, their unique assembly as genotypes and availability as experiences, to form combinations favorable for disease. And it is this particularity that determines who gets which disease at what time in life. The qualities of diseases are expressions of unique and variable human genomes arranged in a gradient of selective effect, a representation of the removal in early life of those unlikely to reproduce, and in postreproductive life, a less-intense test of survival in a variable environment. It is in the latter part of the range of the gradient that both prevention and treatment are likely to be most effective; prevention because changes in environment can be effective in avoiding disease, and treatment because the homeostasis can be characterized as inefficient and in need of a boost, rather than broken. The logic of prevention is more powerful than that of treatment, but we need both a more comprehensive knowledge of nongenetic proximate causes and, in time, to learn, understand, and adjust to the social dislocations any sudden spate of preventions could bring. But it is in part in the grasp of the possibility and plausibilities of both prevention and treatment, and in part in understanding the meaning in medicine of individuality and the virtues of population thinking in relation to it, that we may be able at once to pursue the reductionist path we have so successfully traversed and return to embrace the integration, the humanity, of patients who appeal to us for relief of both the consequences of their molecular incongruities and the injury of the disease to that integrated humanity.

### Biographies

**Barton Childs, MD** (1916–2010) was emeritus professor of pediatrics at the Johns Hopkins University School of Medicine. He attended medical school there and, with brief sojourns studying at Boston Children’s Hospital and University College London, spent nearly 70 years as a devoted clinician, teacher, mentor and investigator in Baltimore. He was the first to prove that X-inactivation occurred during early human embryogenesis, thus confirming the Lyon hypothesis. He was one of the first to develop and endorse genetic counseling as a clinical specialty before the advent of dedicated training programs and formal certification. Perhaps his greatest contribution was his commitment to introducing genetics into educational curricula at all levels of instruction, especially throughout medical school. The current curriculum at Johns Hopkins, “From Genes to Society,” is based largely on his perceptions. His numerous awards included the William Allan Award of the American Society of Human Genetics, the Johns Howland Award in pediatrics, and the Research Career Award of the National Institutes of Health. He worked avidly and incessantly for nearly 30 years after attaining emeritus status. During this time he published *Genetic Medicine: A Logic of Disease*, which should be required reading for any student of medicine or human biology.

**Reed Pyeritz** completed his PhD and MD at Harvard and trained in internal medicine at the Peter Bent Brigham Hospital in Boston and medical genetics at the Johns Hopkins Hospital in Baltimore. He is a professor of Medicine and Genetics at the Raymond and Ruth Perelman School of Medicine of the University of Pennsylvania in Philadelphia, where he directs the Center for the Integration of Genetic Healthcare Technologies and serves as vice-chair for academic affairs of the Department of Medicine. He is a senior fellow in both the Center for Bioethics and the Leonard Davis Institute for Health Economics.

His research has focused on several areas, including clinical investigations of heritable disorders of connective tissue and cardiovascular diseases, especially those affecting the thoracic aorta. Currently he is studying how more refined methods of investigating genetic variation, such as cytogenomic arrays and whole genome sequencing, actually increase the level of uncertainty in applying the results clinically.

### 3.1 INTRODUCTION

Genes are major determinants of human variation. Genome-sequencing studies have shown that an individual genome includes 10,000–11,000 differences from the reference genome that change an amino acid in a protein (non-synonymous change) and an approximately equal number of synonymous variants. Any individual is heterozygous for 50–100 variants that have been associated with genetic disorders (1). The impact of genetically determined characteristics spans a continuum and may be nil at one extreme or lethal at the other. In determining a trait, one or two alleles may be all important, but more commonly genes interact with one another and with one or more environmental factors. This interaction between genetic and environmental factors is now apparent for numerous conditions and includes many previously believed to have a purely environmental etiology. For example, genetically determined susceptibility has now been identified for several infections, for many drug-induced idiosyncrasies, and for several carcinogens (e.g. bladder cancer in aniline dye workers who are slow acetylators). We suspect that such interactions are commonplace and that relatively few conditions are solely environmental in causation. In addition to the environment, interactions with the microbiome, epigenetic modifications resulting in altered gene expression,

and chance all influence how the genome translates into a phenotype.

### 3.2 FREQUENCY OF GENETIC DISEASE

For definitions of the types and frequency of genetic disorders, we use the currently available information, with the proviso that these are all the minimum frequencies and are based on imperfect categorization. Interpretation of what constitutes a genetic disorder will depend on the situation (e.g. red–green color blindness may be a serious disability to the hunter-gatherer) or on the public perception (e.g. persons with albinism are considered blessed in some populations). Hence, the distinction between normal variation and disease is blurred and, as variable criteria have been used in different surveys of genetic disease, this must be considered in their interpretation. The situation is further complicated by the continued delineation of new phenotypic subtypes and by population variations in the frequencies of different genetic disorders. Thus, most of the available data pertain to specific conditions either in a sample of the general population or in specific populations (e.g. the learning disabled); extrapolation to the overall population is difficult.

#### 3.2.1 Chromosomal Disorders

By definition, a chromosomal disorder is present if there is a visible alteration in the number or structure of the chromosomes. Using routine light microscopy and a moderate level of chromosome banding, the frequency

<sup>†</sup>Deceased.

of balanced and unbalanced structural rearrangements in newborns has been estimated at about 9.2/1000 (2). Some of those with unbalanced rearrangements will have congenital anomalies and/or intellectual disabilities. A proportion of those with balanced changes will, in adult life, be at increased risk of either miscarriage or having a disabled child. The incidence of aneuploidy in newborns is about 3/1000, but the frequency increases dramatically among stillbirths or in spontaneous abortions (3). Different types of chromosomal abnormalities predominate in spontaneous abortions as compared with live-born infants. For example, trisomy 16 is the commonest autosomal trisomy in abortions, whereas trisomies for chromosomes 21, 18, and 13 are the only autosomal trisomies occurring at appreciable frequencies in live-born infants. Monosomy for the X chromosome (45,X) occurs in about 1% of all conceptions, but 98% of those affected do not reach term. Triploidy is also frequent in abortions, but is exceptional in newborns. The high frequency of chromosomally abnormal conceptions is mirrored by results of chromosome analysis in gametes, which reveal an approximate abnormality rate of 4–5% in sperm (4) and 12–15% in oocytes (5).

Routine light microscopy cannot resolve small amounts of missing or additional material (less than 4Mb of DNA). The advent of genomic microarray analysis has revealed a high frequency of submicroscopic deletions and duplications and other copy-number variations, including both apparently benign and pathological changes (6). Multiple microdeletion and microduplication disorders have been defined in recent years and undoubtedly more await discovery (see Chapter 29). Such microdeletions, which epistemologically link “chromosomal disorders” with single-gene disorders, account for a proportion of currently unexplained learning disability and multiple malformation syndromes (7).

### 3.2.2 Single-Gene Disorders

By definition, single-gene disorders arise as a result of mutations in one or both alleles of a gene on an autosome or sex chromosome or in a mitochondrial gene. There have been many investigations into the overall frequency of single-gene disorders. Many early estimates were misleadingly low due to under-ascertainment, especially of late-onset disorders (e.g. familial hypercholesterolemia, adult polycystic kidney disease, and Huntington disease). Carter (8) reviewed the earlier literature and estimated an overall incidence of autosomal dominant traits of 7.0 in 1000 live births, of autosomal recessive traits of 2.5 in 1000 live births, and of X-linked disorders of 0.5 in 1000 live births. This gave a combined frequency of 10 in 1000 live births (1%). At that time, approximately 2500 single-gene disorders had been delineated. The number of recognized Mendelian phenotypes has since almost doubled, and these new entities include several particularly common conditions (e.g. familial breast cancer syndromes, with a combined

estimated frequency of 5 in 1000; hereditary nonpolyposis colon cancer syndromes, with a combined frequency of 5 in 1000). In addition, new technologies for DNA analysis have revealed a higher-than-expected frequency of generally asymptomatic people with one or two mutant alleles at a locus (1). For example, up to 1% of the population has a mutant allele for von Willebrand factor, but many of these people have a few or no symptoms, so again there is the problem of the imprecise and variable boundary between a harmless variant and a clinically important one. Furthermore, DNA analysis has shown that for several important disorders, including myotonic dystrophy and fragile X syndrome, relatives of an affected individual may harbor a premutation that, although not detrimental to the carrier, has the potential for expansion to a full deleterious mutation in an offspring. The prevalence of such premutation carriers may be as high as 1 in 178 females for fragile X syndrome (9).

The frequencies of many single-gene disorders show population variation. Geographic variation may be explained by selection or by founder effects or may be attributed to random genetic drift. Selection has resulted in a carrier frequency of 1 in 3 for sickle cell anemia in parts of equatorial Africa, and the Afrikaners of South Africa have a high frequency of variegate porphyria and familial hypercholesterolaemia due to a founder effect. The carrier frequency for mutations in *HFE*, one of the genes responsible for hemochromatosis, is 1 in 10 in individuals of Celtic ancestry. Undoubtedly, more single-gene disorders are going to be delineated. In theory, at least one per locus will eventually be recognized (about 20,000) minus those with no or a mild phenotype and minus those incompatible with establishment/continuance of a pregnancy. Increasing the total are those loci for which different mutations cause entirely different phenotypes. For example, mutations in *LMNA* can result in at least 13 distinct disorders (10). There is also an overlap with the multifactorial category. For example, many patients with acute intermittent porphyria are asymptomatic in the absence of an environmental trigger, and epistatic involvement of other genes is believed to contribute to intrafamilial phenotypic variation for patients with the same mutation. As more gene–environment and gene–gene interactions are identified, the boundary between single-gene disorders and multifactorial disorders will become further blurred.

### 3.2.3 Multifactorial Disorders

Multifactorial disorders result from an interaction of one or more genes with one or more environmental factors. Thus, in effect, the genetic contribution predisposes the individual to the actions of environmental agents. Such an interaction is suspected when conditions show an increased recurrence risk within families, which does not reach the level of risk or pattern seen for single-gene disorders and

when identical twin concordance exceeds that for non-identical twins, but is less than 100% (see Chapter 14). For most multifactorial disorders, however, the nature of the environmental agent(s) and the genetic predisposition are currently unclear and are the subject of intensive research efforts. The ability to conduct genome-wide association studies has accelerated progress in this area.

Multifactorial disorders are believed to account for approximately one-half of all congenital malformations and to be relevant to many common chronic disorders of adulthood, including hypertension, rheumatoid arthritis, psychoses, and atherosclerosis (complex common disorders). The former group had an estimated frequency of 46.4 per 1000 in the British Columbia Health Surveillance Registry (11). In addition, a multifactorial etiology is suspected for many common psychological disorders of childhood, including dyslexia (5–10% of the population), specific language impairment (5% of children), and attention deficit-hyperactivity disorder (4–10% of children). Hence, the multifactorial disorder category represents the commonest type of genetic disorder in both children and adults. Multifactorial disorders also show considerable ethnic and geographic variation. For example, talipes equinovarus is some six times more common among Maoris than among Europeans, and neural tube defects were once 10 times more frequent in Ireland than in North America.

Often ignored, both intellectually and in research, are genotypes that reduce susceptibility to potentially harmful environmental factors. An understanding of alleles that provide protection from disease or increase longevity will yield insight into pathogenesis as well as novel approaches to therapy and prevention.

### 3.2.4 Somatic Cell Genetic Disorders

Somatic cell mutation is a natural developmental process in the immune system, but is also responsible for a significant burden of genetic disease. This includes somatic or germline mosaicism for single-gene disorders (12), as well as mutations that give rise to cancer (see Chapter 21). Cancer cells tend to have accumulated multiple mutations; the first step in the cascade of mutations may be inherited (i.e. involving germ cells and all somatic cells). Carcinogens are important causes of noninherited mutations, and genetic susceptibility is suspected to account for individual variation in risk on exposure. Somatic-cell genetic disorders might also be involved in other clinical conditions such as autoimmune disorders and the aging process.

## 3.3 MORBIDITY AND MORTALITY DUE TO GENETIC DISEASE

The same general difficulties that pertain to the frequency estimates for genetic disorders also apply to estimates of

the contribution of the various types of genetic disorders to morbidity and mortality during pregnancy, in childhood, and in adulthood. Hence, these figures should be taken as minimum estimates.

### 3.3.1 Conception and Pregnancy

One in 15 recognized pregnancies spontaneously leads to miscarriage, and a higher percentage (up to 50%) of conceptions is lost before recognition of the pregnancy. The majority of these losses are caused by numerical chromosomal abnormalities.

### 3.3.2 Childhood

Since the turn of the century in many Western countries, advances in medicine and public health have resulted in a gradual decline in the contribution of environmental factors to childhood morbidity and mortality. The result of these changes has been to throw genetic disorders into greater prominence. By contrast, in developing countries, non-genetic causes of childhood mortality continue to predominate. An idea of the contribution of genetic disease to morbidity can be judged from the prevalence of such diseases among pediatric inpatients. In reviewing 4115 inpatients, Hall and colleagues (13) found multifactorial disease in 22.1%, a single-gene disorder in 3.9%, and a chromosomal disorder in 0.6%. Thus, more than 1 in 4 pediatric inpatients have a genetic disorder in one of these categories, as compared with the general population frequency estimate of 1 in 20 by 25 years of age. This does not include the morbidity that does not lead to inpatient admission. An updated survey by McCandless et al. revealed 71% of children admitted to the hospital to have a disorder with a significant genetic component (14). Stevenson and Carey (15) have found that 34.4% of deaths among children hospitalized in a tertiary care center could be attributed to congenital anomalies, of which 16.7% were due to chromosomal abnormality and 11.7% due to a recognized malformation syndrome.

### 3.3.3 Adulthood

In Western countries, the commonest causes of death are cancer and cardiovascular disease. All cancers are now known to have a cumulative somatic-cell genetic basis, and there is evidence for a major genetic contribution to cardiovascular disease. Single-gene disorders causing diabetes or high blood pressure are relatively uncommon, but multifactorial inheritance accounts for a large proportion of patients with premature vascular disease and systemic hypertension. Similarly, there is a growing recognition of the importance of multifactorial inheritance for many other common disorders of adulthood responsible for both morbidity and mortality.

## Biographies

**Bruce R Korf, MD, PhD.** Dr Korf received his MD degree from Cornell University Medical College and his Ph.D. degree in genetics and cell biology from Rockefeller University. He then completed training in pediatrics, pediatric neurology, and genetics at Children's Hospital, Boston. He served as clinical director in the Division of Genetics at Children's Hospital from 1986 to 1999 and as the medical director of the Harvard-Partners Center for Genetics and Genomics from 1999 to 2002. Currently he is the Wayne H and Sara Crews Finley Chair in Medical Genetics, Professor and Chair, Department of Genetics and Director, Heflin Center for Genomic Sciences at University of Alabama at Birmingham. Dr Korf has completed terms as president of the Association of Professors of Human and Medical Genetics, President of the American College of Medical Genetics, member of the boards of directors of the American College of Medical Genetics and the American Society of Human Genetics, member of the Liaison Committee on Medical Education, and the National Cancer Institute Board of Scientific Counselors. He currently is President of the ACMG Foundation for Genetic and Genomic Medicine and serves on the Board of Scientific Counselors of the National Human Genome Research Institute.

**Reed Pyeritz** completed his PhD and MD at Harvard and trained in internal medicine at the Peter Bent Brigham Hospital in Boston and medical genetics at the Johns Hopkins Hospital in Baltimore. He is a professor of Medicine and Genetics at the Raymond and Ruth Perelman School of Medicine of the University of Pennsylvania in Philadelphia, where he directs the Center for the Integration of Genetic Healthcare Technologies and serves as vice-chair for academic affairs of the Department of Medicine. He is a senior fellow in both the Center for Bioethics and the Leonard Davis Institute for Health Economics.

His research has focused on several areas, including clinical investigations of heritable disorders of connective tissue and cardiovascular diseases, especially those affecting the thoracic aorta. Currently he is studying how more refined methods of investigating genetic variation, such as cytogenomic arrays and whole genome sequencing, actually increase the level of uncertainty in applying the results clinically.

## Genomics and Proteomics

*Raju Kucherlapati*

### 4.1 GENES AND HUMAN DISEASE

The last century has witnessed the increasing realization that genetics plays an important role in human health and disease. The principles underlying genetics were discovered by Mendel in 1867, but remained obscure until the beginning of the twentieth century. Archibald Garrod first enumerated the significance of these genetic principles to human disease in 1902 (1).

The initial focus of human genetics was the class of diseases and disorders that were the result of mutations in single genes. Because the inheritance of these disorders follows the rules established by Mendel's discoveries, these disorders are referred to as Mendelian disorders. Because the disorders are the result of mutations in single genes, they are also referred to as single-gene disorders. Much of the twentieth century was devoted to the description of a large number of such disorders. A compilation of these disorders that is available online (Online Mendelian Inheritance in Man (OMIM) (2)) lists more than 10,000 such disorders. Many of these disorders were discovered in newborn children. Although all of these single-gene disorders collectively constitute a significant health burden on the population, the relative rarity of each of the disorders made human genetics an esoteric specialty of medicine.

The realization that genetics plays an important role in common as well as rare disorders is changing the importance of this science in research and clinical medicine. Assessment of risk factors for many common disorders, such as cancer, cardiovascular disease, obesity, diabetes, and neurologic/neurodegenerative diseases, to name only a few, has revealed that one of the greatest risk factors for developing a disease is having a close relative who is affected by the disorder. Since close relatives share many genes in common, it is reasonable to conclude that genes play an important role in the etiology of these disorders. Dramatic illustration of the role of genetics in common disorders came from the studies of twins. Identical twins share all of their genetic information and fraternal twins are like siblings, who, on the average, have a 50% probability of being identical at any genetic locus. Therefore, if one member of the twin has a disorder that has a genetic

basis, the probability that the second member also has the disease (concordance) would be very high in identical twins and no more than 50% in fraternal twins (3). For example, the concordance rate of diabetes and obesity in identical twins is as high as 90%, while in fraternal twins it is less than 50% (4). These types of studies have shown that many of the common disorders have a genetic basis.

In addition to the changes of genes in the germ line, somatic genetic changes also play a very critical role in many diseases, especially those that involve clonal expansion of cells, such as cancer. For example, somatic mutations in the gene *TP53* are found in more than 50% of all human cancers.

Germ line or somatic changes that involve whole chromosomes or parts of chromosomes are also important for human disease. Complete or partial trisomy (three copies of a chromosome) of chromosome 21 leads to Down syndrome, and chromosome number changes (aneuploidy) and segmental amplifications or loss of individual genes or areas of the genome are common features in many solid tumors.

Detection of chromosomal, sub-chromosomal, or individual gene changes can help understand the etiology of many human diseases. In addition, the ability to accurately detect these changes also has implications for diagnosis, prognosis, and treatment of human disease.

### 4.2 GENOMICS

The term genomics was first coined by Thomas Roderick of the Jackson Laboratory and was used to create a new scientific journal in 1987. This term is now used to define an area of science. While genetics is the study of patterns of inheritance and the study of single genes, genomics is the study of the organization of the entire genome as well as the study of the functions and interactions of large sets of genes or the whole genome.

One of the early contributions of genomics is the facilitation of disease gene identification. The identification and study of disease genes required novel technologies. The advent of recombinant DNA technologies and the polymerase chain reaction (PCR) in the last third of

the twentieth century allowed identification of several disease genes. Protein sequencing methods identified the basis for certain diseases such as sickle cell anemia, and the cloning of genes corresponding to abundant messenger RNAs allowed confirmation of the genetic basis for some blood-borne diseases. This approach, however, required that we have the knowledge about the protein whose lack or alteration in function causes the disorder. Since the molecular basis for many of the human diseases is not known, and in many cases even the particular organs where the gene product is critical are not known, a directed approach for gene cloning is not possible.

Positional cloning, an alternative approach to cloning genes based on their position in the genome, has been developed (5). In this approach, genetic methods are used to localize the disease locus to a relatively small segment of the genome, all of the genes in that interval are identified, and the sequence of each of the genes is compared between affected and unaffected individuals, preferably among closely related individuals. The gene that shows a mutation among the affected individuals would be the disease-causing gene.

To facilitate disease gene discovery and to form the foundation for understanding the complete set of genetic instructions in the human genome, an international effort was initiated in the early 1990s to map and sequence the human genome. These efforts culminated in the development of a draft sequence of the human genome in 2001 (6) and the completed sequence in 2003 (7), which coincided with the 50th anniversary of the discovery of the structure of DNA.

### 4.3 MAPPING THE HUMAN GENOME

The maps of the human genome that were constructed can be generally classified into two categories: genetic maps and physical maps.

#### 4.3.1 Genetic Maps

Construction of genetic maps requires three components:

1. Genetic markers that are polymorphic in the population.
2. Robust methods for analyzing the markers in an appropriate set of pedigrees.
3. Analytical methods to construct the maps.

Early markers for construction of genetic maps were immunologic markers such as the ABO, MN, and Rh blood groups. In the 1970s, the discovery that enzymes could exhibit polymorphisms that resulted from changes in charge (isoenzymes) led to widespread use of such markers. A revolution in genetic mapping of humans was facilitated by the discovery of DNA-based polymorphisms. The focus on such markers was based on natural variation in the presence or absence of restriction enzyme

recognition sites. Let us consider a fragment of DNA that can be recognized by the restriction enzyme EcoRI to be 5 kbp in length. If, in a certain subset of the population, there were a single nucleotide change at one of the two recognition sites that define the particular 5 kbp fragment, EcoRI digestion would result in a fragment that is larger than the 5 kbp fragment (Figure 4-1).

Such polymorphisms are termed restriction fragment length polymorphisms (8). Because this is a DNA-based assay, use of a single restriction enzyme and an array of unique probes from different portions of the genome enable the detection of many different regions of variation. Such polymorphisms can only be bimorphic (presence or absence of the recognition site). For genetic analysis, the degree of heterozygosity of the markers determines their utility. If there are two alleles of a locus and they are in Hardy–Weinberg equilibrium, the degree of the heterozygosity can be ascertained by the simple formula  $2pq$ , where  $p$  = the frequency of one allele and  $q$  = the frequency of the second allele. If the two alleles are present with equal frequency ( $p$  and  $q = 0.5$ ), the degree of heterozygosity would be  $2(0.5)(0.5) = 0.5$ . If one allele is present at low frequency (e.g.  $p = 0.9$  and  $q = 0.1$ ), the heterozygosity would be much lower:  $2(0.9)(0.1) = 0.18$ . Therefore, for a biallelic marker the maximum heterozygosity would be 0.5.

The discovery and the use of microsatellite markers (9,10) made genetic mapping easier. This was based upon the observations that there are a variety of repetitive sequences that are located within the genome and that the number of individual elements within the repeats is highly polymorphic in the population. For example, there are regions in the genome that contain one (mono; e.g. AAAAAA), two (di; e.g. CACACACA), three (tri), and four (tetra) nucleotide repeats. Very often the number of the individual repetitive elements at these regions is highly variable. Since such variations have occurred

**FIGURE 4-1** As a result of a single nucleotide change at one of the two recognition sites that define a particular 5 kbp fragment, EcoRI digestion results in a fragment that is larger than the 5 kbp fragment.

many, many generations ago, the repeat sizes are stably transmitted from one generation to the next. The variation in repeats can be analyzed by using PCR primers for unique sequences that flank the repeats and the separation of the products in high-resolution gels that can distinguish small differences in the length of the products (11). The high degree of polymorphism of these markers results in a high degree of heterozygosity in the population (sometimes as much as 0.8 or more).

The microsatellite markers are now being replaced by single nucleotide polymorphisms (SNPs). Sequencing of individual genes or portions of other regions revealed that any two unrelated individuals differ at approximately 1 in every 1000 nucleotides (9). Although such differences are usually bimorphic and heterozygosity at any one marker might be low, such polymorphisms can be easily and inexpensively assayed. Strategies for using such markers in genetic analysis were proposed (12–14). Methods to detect a very large number of such polymorphisms are now becoming available.

The use of all of these different types of markers has enabled the construction of several different genetic maps of the human genome. The strategy for construction of genetic maps involved the use of DNA samples from a set of multigenerational families and using the information to assess frequencies of recombination between pairs of markers. The genetic map is a reflection of the frequency of genetic recombination. Any Mendelian disease that is segregating in a family or a set of families can be considered as a genetic marker and can be mapped and placed within the genetic map. The unit of genetic recombination is percent recombination, and 1% recombination is equal to a genetic distance of 1 centimorgan (cM). The length of the human genome in recombination units is 3000 cM. Since the physical size of the human genome (see later) is about  $3 \times 10^9$  bp, 1% recombination frequency corresponds to approximately  $10^6$  bp of DNA.

### 4.3.2 Physical Maps

Physical maps of the genome proved to be valuable as a prelude to clone-by-clone-based sequencing and now serve as useful tools for identifying and examining small, well-defined cloned portions of the genome.

The first physical map of a eukaryote that was constructed was that of the yeast *Saccharomyces cerevisiae*. To construct a physical map, a genomic phage library (fragments of DNA that were cloned into a bacteriophage vector) was made. DNA from individual clones was digested with a restriction endonuclease and the products were separated by gel electrophoresis. The resulting pattern from each clone is defined as a “fingerprint.” If two clones have sequence overlaps, they would share a part of the fingerprint profile (15). Therefore, overlaps between clones can be established. As overlaps are established, the clones begin to coalesce and form

contiguous segments referred to as “contigs.” At early stages of assembly, each individual clone will constitute a contig, and therefore the size of individual contigs will be equal to the size of the clone. As the contigs merge, their size increases; ultimately, each chromosome will be represented by a single contig.

Although clone-based fingerprinting played an important role in human genome mapping (16,17), the much larger size of the genome required the development of novel strategies and approaches to accomplish the goal. Two methods became particularly useful: radiation hybrid (RH) mapping and sequence-tagged site (STS) mapping.

**4.3.2.1 RH Mapping.** When human cells are irradiated with ionizing radiation, they suffer chromosomal breaks. The number of such double-stranded breaks per cell is proportional to the level of irradiation. Levels of irradiation that cause one or more breaks per chromosome are lethal to the cells; however, the irradiated human cells can be rescued by fusion to a normal cell. Goss and Harris showed that this feature could be used to map genes (18). A normal human cell type is irradiated and fused with a rodent cell. The somatic cell hybrids retain a random subset of the chromosomal fragments. A panel of independent RHs would retain different and random segments of the human genome. The closer two markers are along the length of a chromosome, the lower the possibility of breakage between them. Therefore, frequency of co-retention of any two markers would reflect their relative distance apart.

A panel of RH cell lines was generated and screened with PCR-based markers. Like genetic maps, co-segregation of markers was reflected as units that are called centirays for a given level of irradiation (19).

**4.3.2.2 STS Maps.** Construction of RH maps and other physical maps required easily detectable markers. STS markers are one such set of markers. A pair of PCR primers that amplify a unique region of the genome defines each of the STS markers. Such markers are very robust because they define a unique region of the genome, and they can correspond to genes, polymorphic markers, or anonymous regions of nonrepetitive DNA (17). A global physical map of the human genome was constructed using this approach.

STS markers that corresponded to polymorphic regions were used for genetic mapping, and all types of STS markers were used for RH mapping and for identifying individual-cloned DNA fragments from libraries and for establishing clone overlaps and building contigs.

A number of different types of genomic DNA libraries proved useful in making physical maps. Unlike yeast maps, in which short-insert libraries played an important role, human physical map construction required large-insert clones. Initial efforts were focused on the use of yeast artificial chromosome (YAC) libraries (20). Although YAC vectors could take DNA fragments from as low as a few hundred kilobases to as large a segment

**FIGURE 4-2** If two YACs share a set of STS markers, they are considered to have an overlapping DNA sequence. The order of the markers and the relative orientation of the YACs can be deduced by the patterns of overlap. The strategy used to accomplish this goal is shown here.

as a megabase ( $10^6$ bp) or more, they proved to be unstable and had a tendency to be chimeric. Nevertheless, they proved to be valuable in constructing physical maps. Genomic libraries of human DNA in YACs were screened with large numbers of STS markers. Each YAC was defined by the set of STS markers it contained. If two YACs share a set of STS markers, they would be considered to have an overlapping DNA sequence. The order of the markers and the relative orientation of the YACs can be deduced by the patterns of overlap. The strategy that was used to accomplish this goal is shown in Figure 4-2. An actual physical map for a part of human chromosome 12 is shown in Figure 4-3.

The RH-based and YAC-based maps, in combination with genetic maps, provided an excellent framework for more detailed physical maps of the human genome that were based on the use of inserts from a set of bacterial cloning vectors such as cosmids and bacterial artificial chromosomes (21,22).

#### 4.4 SEQUENCING THE HUMAN GENOME

Two different approaches were used to obtain the sequence of the human genome. In one approach, the basic unit of sequencing was a cloned segment of DNA and the second approach involved a genomic shotgun approach. In the clone-based approach, DNA from a defined segment of the DNA that corresponded to a particular human chromosome was used to construct a random fragment (shotgun), small-insert library. Members of this library were sequenced, and automated methods were used to assess overlaps and to assemble the sequence into a contig that corresponded to the original large-insert clone. Sequencing overlapping clones allowed assembly of the sequence for each chromosome (23). In the random clone-sequence approach, total human DNA was randomly fragmented, cloned into sequencing vectors, and sequenced. Automated methods were used to assess overlaps of sequence information from different clones and to assemble the sequence (6).

Draft sequences of the human genome were published in 2001, and a completed version of the sequence was described in 2004 (6,7,23). The human genome is composed of approximately  $2.7 \times 10^9$ bp of DNA, and current estimates suggest that it encodes approximately 23,000 genes.

#### 4.5 CURRENT APPROACHES TO SEQUENCE PARTS OR THE WHOLE HUMAN GENOME

There has been a revolution in the methodologies and the cost of DNA sequencing that in turn is greatly facilitating the identification of human disease genes. Much of the first human genome sequencing was achieved by the use of dideoxynucleotide sequencing, also referred to as Sanger sequencing named after the Nobel Prize-winning biochemist Frederick Sanger. In this method, a sequencing reaction mixture contained normal nucleotides and small portions of a dideoxynucleotides. Whenever a dideoxynucleotide is incorporated into the DNA sequence, it prevents the addition of additional nucleotide, thus generating DNA molecules of varying size that end at the site of the incorporation of the dideoxynucleotide. Separation of these molecules on the basis of their size on automated DNA sequencers enables rapid sequencing of the molecule. In the later stages of the human genome project, DNA was fractionated in 96 capillary gel matrices and the sequence lengths of several hundreds of nucleotides per capillary were achieved.

The rapidity with which DNA sequences can be generated and the cost of obtaining them has dramatically changed since 2001. Although there are several different platforms for rapidly sequencing DNA, the basic principle involves generating millions of microscopic spots in a small region, each corresponding to a single DNA molecule, deposited in a matrix and the positions of all of the molecules recorded optically. In one method, a single-tagged nucleotide is added to the reaction mixture and the polymerase is allowed to add that single nucleotide to the appropriate DNA molecule. Imaging after this reaction would record all the spots that have incorporated that nucleotide. A second nucleotide is added to the reaction mixture and the spots that incorporate the nucleotide are recorded. This process is completed with all four nucleotides and the process repeated again. Deconvolution of the images allows the deduction of the sequence of DNA at each spot. Alignment of the resulting sequences to a standard genomic sequence would allow assembly of the DNA sequence. As millions of DNA molecules can be simultaneously sequenced, large amounts of DNA sequence can be generated in a relatively small amount of time at a significantly reduced cost (24). For example, it was estimated that the completion of the human genome

sequence cost US\$2–3 billion while current technologies can accomplish the same goal for US\$10,000 or less.

During the past few years, technologies to capture specific subsets of the human genome have also been developed. Using these methods, it is possible to sequence tens to hundreds of genes or the exomes of all genes for a fraction of the cost of the whole genome sequencing. These technologies are revolutionizing identification of human disease genes.

## 4.6 AN APPROACH FOR CLONING HUMAN DISEASE GENES

For Mendelian disorders, a well-established approach to clone the disease gene is to identify one or a set of multi-generational families in which this disorder is segregating and map the disease locus onto the genetic map. Once a disease gene locus is mapped to a large interval, it is possible to narrow the location by using additional markers in that region. Once the location is narrowed down to a 1–2cM interval, it is possible to identify all of the genes encoded in that region and sequence them in the affected individuals. A gene that consistently has a mutation in the affected individuals but not in the unaffected individuals is most likely the disease gene (5). This approach has been successfully used to clone a large number of genes. Among the early genes that were cloned are those for cystic fibrosis (13), neurofibromatosis (25,26), and Huntington disease (27). In the early stages of disease gene cloning based upon the location of the gene, it was necessary to narrow down the region in which the disease gene was likely to be present to a relatively small region and therefore a small number of genes. The advent of massively parallel sequencing approaches described above are changing the landscape, and examples of whole-exome sequencing or whole genome sequencing of a single affected individual are becoming more commonplace (28).

### 4.6.1 Association Studies

The availability of the human DNA sequence has also allowed us to define the genetic variation among individuals. That definition, in turn, is permitting us to identify the genes that may be involved in complex disorders.

Sequencing genes or parts of the genomes from different individuals revealed that there is natural variation in the DNA sequence. On average, any two individuals differ at approximately 1 of every 1000 nucleotides (9,11,12,14). Most such variation is at the single nucleotide level and is referred to as a SNP. The frequency of any single polymorphism within a given population is variable and depends on the time of its origin in the human history: the older the origin, the more frequent it is in the population. Each of the DNA sequence variants can be used as a polymorphism and can serve as a genetic marker. SNPs can be used like any other genetic marker

to map a genetic locus. SNPs can also be used to conduct association studies. If a common disease has a genetic basis, the disease-causing allele and genetic markers that are closely linked to it will be present at much higher frequencies in the affected cohort of individuals. Examination of the DNA from a set of cases and controls for a large set of SNPs would reveal any association between the disease and genetic markers. A large number of such associations have been described and confirmed (29).

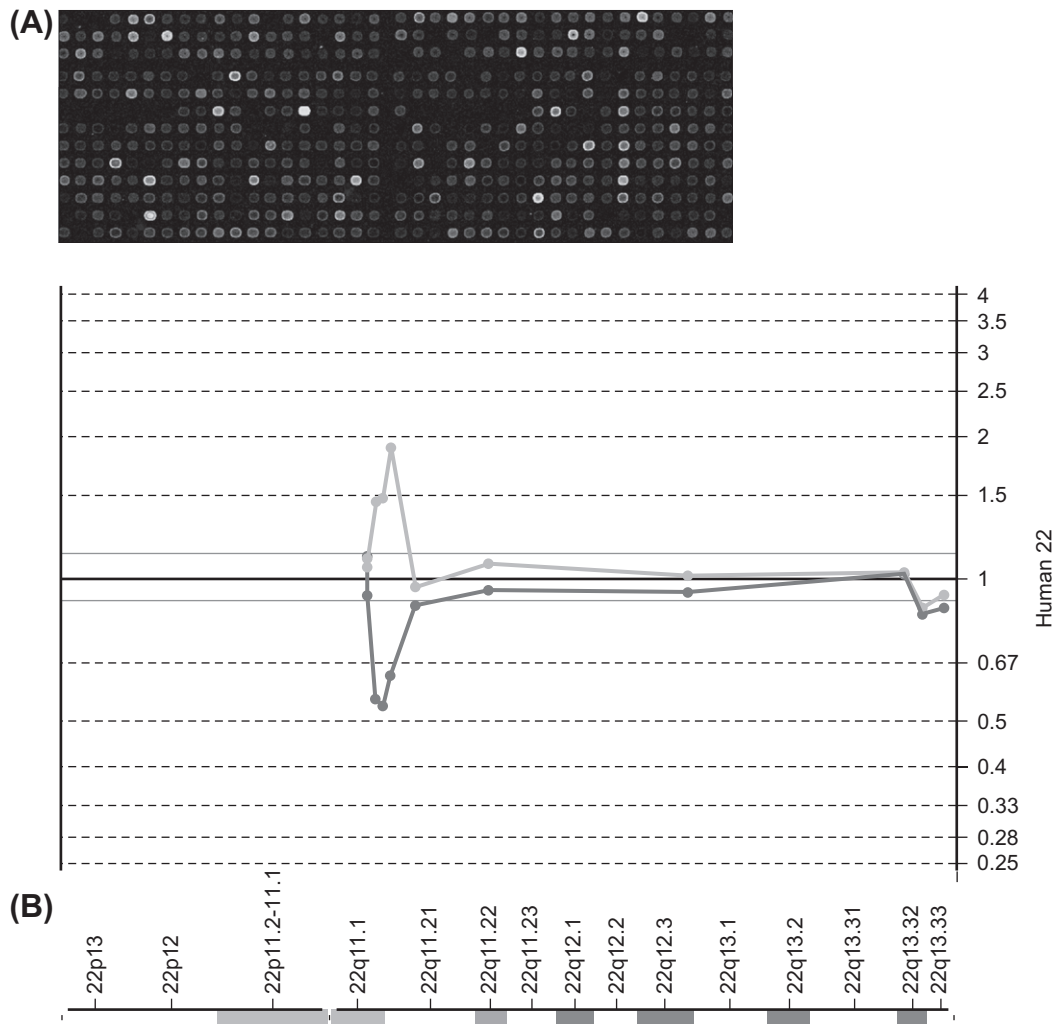

### 4.6.2 Genomic Changes

Alterations in the genome in the germ line or soma may have profound implications for disease. For example, certain types of chromosome number abnormalities result in specific disorders. Increase in the number of copies of chromosome 21 from two to three results in Down syndrome. Reduction in the copy number of a portion of chromosome 22 from two to one causes DiGeorge/velocardiofacial syndrome (30). Increase in the copy number of the same region from two to three results in der(22) syndrome (31). Whole chromosome number changes are very common in many solid tumors and increases of copy numbers of specific regions of the genome thorough amplification or loss of heterozygosity of specific regions or particular chromosomes are also common features in solid tumors (32). Detection of these chromosomal changes has implications for diagnosis and prognosis of disease. Different methods are available to detect specific chromosomal or sub-chromosomal changes.

**4.6.2.1 Cytogenetics Methods.** Examination of metaphase chromosomes is a common method for determining chromosomal and sub-chromosomal changes. Because chromosomes are highly condensed during metaphase, the resolution of this method for detecting chromosomal changes is several megabases of DNA. Preparation of metaphase chromosomes for examination requires that the cells be undergoing mitosis. Nonmitotic or interphase cells can also be used for detection of copy number changes by hybridization of the cells' DNA with targeted probes that correspond to known regions of the genome. This method is referred to as fluorescence in situ hybridization. For example, if a chromosome 21-specific probe is used for hybridization, cells from a normal individual reveal two spots corresponding to the two chromosomes. If the cells are from a patient or fetus with Down syndrome, the probe may reveal three spots.

**4.6.2.2 Array-Based Comparative Genomic Hybridization.** A high-resolution method for detecting copy number changes is available. In this method, sequences corresponding to specific known portions of human DNA can be made into an array. DNA from a normal individual labeled with a fluorophore (e.g. green) and DNA from the test sample labeled with a second fluorophore (e.g. red) can be combined and hybridized to the array. The two DNA samples compete with each other to hybridize to the target immobilized DNA. If a particular

**FIGURE 4-4** The relative intensities of two fluorophores can be measured with a high degree of accuracy, providing a sensitive method for detection of copy number changes. An example of how this method was used to detect copy number changes in a part of human chromosome 22 is shown here. (A) Image of an array (B) Relative intensities of the two colors in the hybridization reaction. The region of the spike reveals loss of one copy of that segment.

segment of the DNA is present in equal parts in the reference and sample DNA, the two fluorophores will be equally represented and the spots will be yellow in color (a combination of green and red). If the sequence is overrepresented in the reference, the spot(s) corresponding to it will be green; if it is overrepresented in the test sample, the spot(s) will be red. The relative intensities of the fluorophores can be measured with a high degree of accuracy, thus providing a sensitive method for detection of copy number changes (33). An example of how this method was used to detect copy number changes in a part of human chromosome 22 is shown in Figure 4-4.

#### 4.7 SEQUENCE-BASED METHODS FOR DETECTING CHROMOSOMAL ABNORMALITIES

The new technologies of DNA sequencing described above are also facilitating the rapid discovery of

structural aberrations in DNA. In one approach to DNA sequencing, genomic libraries with insert sizes of 200–300 nucleotides are generated and each molecule is sequenced from both ends and a sequence of 35, 50, or 100 nucleotides is generated. Once the sequence is obtained with a sufficient amount of redundancy and the short reads aligned to the reference genome, it is possible to segment the genome into segments of a desired size (e.g. segments of 1,000 bp) and count the number of reads in each segment. The number of such reads can be compared to a single or pooled control samples. If there is no copy number difference in one or a series of adjacent segments in the control and test samples, the ratio of test/control would be 1.0. If there are copy number variations or amplification of the region of the genome, the ratio would exceed 1.0 and the actual number would depend on the extent of the amplification (a ratio of 1.5 would indicate that the test sample has three copies versus the normal two copies, a ratio of 2 would indicate that

the test sample has four copies versus the normal two copies, etc.). A ratio of less than 1.0 would indicate reduction in copy number. Because the whole genome can be sampled by these sequencing methods, the accuracy and resolution afforded by these methods can be significantly greater than FISH-based or array-based methods.

If the average size of the inserts in the library is 250 bp and 50 nucleotides of sequence was obtained from each end, the pair of reads (mate pairs) would map back to the same chromosome and the distance between the ends of the sequence reads would, on the average, be 150 nucleotides. If there is a 10kb deletion in the genome being sequenced, the mate pairs would map to the same chromosome but would map to regions that are nearly 10kb apart. Since the deletion breakpoints can be mapped to a very small region of the genome, developing appropriate primers that flank the deletion breakpoint, amplifying the region from the test sample, and sequencing that short region would reveal the precise breakpoint at the resolution of a single nucleotide. If the mate pairs map to different chromosomes, it would suggest a translocation. Other chromosomal abnormalities such as inversions and duplications can also be detected by these sequencing methods. The same general approach can be used to sequence RNA. Counting the number of times a transcript is represented in the sequence reads indicates its abundance. Mate pairs would allow detection of alternative splicing products.

### 4.7.1 Gene Expression Profiling

Different genes are expressed in different tissues and cell types. Pathologic changes in particular cells or tissues are often accompanied by changes in patterns of gene expression. Methods to detect changes in expression levels of individual genes are now available. They include Northern blotting, wherein RNA from a target cell type is fractionated by gel electrophoresis, transferred to a nylon membrane, and hybridized with a labeled gene-specific probe. Band intensity is used as a measure of abundance of the corresponding transcript. Quantitative reverse transcriptase-PCR is also a very useful method. The development of array-based methods allows examination of virtually all transcripts in any cell or tissue type. In this method, RNA from a reference sample is converted to its corresponding complementary DNA or RNA, labeled with a fluorophore, mixed with a corresponding complementary DNA or RNA from the test sample labeled with a different fluorophore, and hybridized to an array of DNA fragments corresponding to individual genes (Figure 4-5). Measurement of fluorescence intensities can be correlated to levels of gene expression (34). Sequence-based methodologies are beginning to be used for detecting transcript abundance. When RNA is converted into complementary DNA and subjected to sequencing, the relative number of times a

**FIGURE 4-5** RNA from a reference sample is converted to its corresponding complementary DNA or RNA, labeled with a fluorophore, mixed with a corresponding complementary DNA or RNA from the test sample labeled with a different fluorophore, and hybridized to an array of DNA fragments corresponding to individual genes.

particular RNA is sequenced provides a measure of its abundance.

## 4.8 PROTEOMICS

Proteins are the functional units of cells. Rapid and accurate identification of proteins in cells or body fluids can provide significant information about the functional status of the cell, tissue, or organism. A number of newer methods are becoming available for such analysis.

A proteome is defined as the complete protein complement of a cell, tissue, or organism. The study of the proteome is referred to as proteomics. Although the study of proteins in detail preceded studies of DNA and RNA of organisms, high-throughput methods for detecting and quantitating proteins on a large scale have recently emerged and are continuing to develop. Detection of proteins relied on fractionating methods and gel electrophoresis. Large-scale protein analysis relied on two-dimensional electrophoresis (2DE) and imaging of the spots that result from such a method. Although 2DE is a powerful method, it does not provide for unambiguous assignment of each of the bands to a specific protein. A number of protein analytic methods are now available that are useful in identification of large numbers of proteins. Several of these methods use some type of fractionation of a complex mixture of proteins or peptide fragments followed by mass spectrometry methods to identify individual proteins. In some methods, the mass of a large number of proteins is assessed, thus providing for a profile of the mixture. Differences in the profiles can be used for diagnostic or discovery purposes. In another method, a protein mixture is fractionated and individual fractions are digested with a protease; mass spectrometry is used to deduce the mass of the peptide as well as to sequence that peptide. The availability of genomic sequence allows us to predict the proteins that the genome encodes, and computational comparison of the database containing all of the predicted proteins and peptides allows for unambiguous identification of the origin of the peptide that was sequenced by the mass spectrometer.

## GLOSSARY

- Association Studies** – assessing relationships based on specific genetic or physical features with particular traits.
- Comparative Genomic Hybridization** – a method to detect changes in copy number in different individuals or on the development of tumors.
- Genetic Maps** – maps based on genetic recombination frequencies.
- Genomics** – study of the organization of the entire genome as well as the study of the functions and interactions of large sets of genes or the whole genome.
- Physical Maps** – maps based on physically defined entities such as fragments of DNA.
- Proteomics** – study of protein composition on a large scale.

### Biography

**Dr Raju Kucherlapati, PhD**, is the Paul C Cabot professor in the Harvard Medical School Department of Genetics. He is also a professor in the Department of Medicine at Brigham and Women's Hospital. Dr Kucherlapati was the first scientific director of the Harvard Medical School–Partners Healthcare Center for Genetics and Genomics. His research focuses on gene mapping, gene modification, and cloning disease genes. During 1989–2001, Dr Kucherlapati was the Lola and Saul Kramer professor of Molecular Genetics and the Chairman of the Department of Molecular Genetics at the Albert Einstein College of Medicine in New York. He was previously a professor in the Department of Genetics at the University of Illinois, College of Medicine. He began his research as an assistant professor in the Department of Biochemical Sciences at Princeton University. He has chaired numerous NIH committees and served on the National Advisory Council for Human Genome Research and the NCI Mouse Models for Human Cancer Consortium. He is also a member of the Cancer Genome Atlas project of the National Institutes of Health. He is a member of the Institute of Medicine of the National Academy of Sciences and a fellow of the American Association for the Advancement of Science. He is a member of Presidential Commission for the Study of Bioethical Issues. Dr Kucherlapati received his BS and MS in Biology from universities in India, and he received his PhD from the University of Illinois at Urbana, as well as conducting postdoctoral work at Yale University.

### 5.1 INTRODUCTION

The chemical structure of genetic material as well as the storage, processing, and transfer of genetic information from one generation to the next are similar in all living organisms. Thus, it was expected that the complexity of the human phenotype would be explained by a significantly higher number of genes in humans when compared with simpler organisms. Surprisingly, instead of the predicted 50,000–150,000 human genes, the sequence of the human genome revealed about 20–25,000 genes, similar to the number of genes in many other organisms. However, analysis of the genome and its products has revealed complexity in the form of exquisite temporal and spatial regulation of gene expression, alternative transcripts derived from a single locus, multiple splice variants (including tissue-specific variants) for most genes, and complex posttranslational modifications of proteins, all of which create endless diversity in gene products and their functions.

Since the initial sequence of the human genome was determined, we have gained tremendous new insights into genome structure such as how the sequence and structure define the complex functions of human cells and how genome architecture can be altered to produce disease. Additionally, how our genome is compared with the sequences of the genomes of closely and distantly related organisms has provided unique insights into evolutionary conservation of gene and protein functions as well as our origins as a species. Technological innovations have facilitated defining the genomic sequences of many individual humans, particularly the polymorphic differences that distinguish individuals, allowing a fuller description of the history of our species and the traits we manifest. We are also at the point where we can conceive of understanding at molecular level the genetic contributions to disease across the human population, facilitating targeted medical intervention based on these findings.

### 5.2 DOUBLE HELIX STRUCTURE, DNA REPLICATION, TRANSCRIPTION, AND MEIOTIC RECOMBINATION

#### 5.2.1 Double Helix

The function of the human genome is to transfer information reliably from parent cells to daughter cells and from one generation to the next. This is carried out in a semiconservative manner. One of the two parental DNA strands of a double helix remains intact in every cell division, serving as a template for copying the sequence. The two DNA strands form the double helix by hydrogen bonding between the nitrogenous bases: guanine (G) pairs with cytosine (C) and adenine (A) pairs with thymine (T) (Figure 5-1). The hydrogen bonds formed between these pyrimidine–purine pairs (guanine and adenine are purines; cytosine and thymine are pyrimidines) stabilize the double helix and ensure that the two complementary strands remain together and in register. The strands are oriented antiparallel to each other, meaning that they run in opposite directions: One strand is oriented in a 5′–3′ direction, whereas the other in a 3′–5′ direction.

#### 5.2.2 Replication

Genetic information is preserved and transmitted by DNA replication, a process that produces two identical copies of the DNA. During this process, the two parental strands separate, and each serves as a template for synthesis of a new complementary strand by an enzyme called DNA polymerase (Figure 5-2). As a consequence, each daughter cell inherits one strand of the parental duplex. Every DNA molecule thus contains a “young” strand that was synthesized in the parental cell during DNA replication and an “old” strand that was inherited from the parental cell and synthesized in the grandparental cell. This semiconservative manner of replication guarantees transmission of intact information from one generation to the next. Remarkably, the genome copies itself through

FIGURE 5-1 Complementary structure of double-stranded DNA.

**Replication****Transcription****Translation**

FIGURE 5-2 Flow of genetic information.

millions of cell divisions during an individual's life with amazing precision. The error rate of about  $1 \times 10^{-8}$  per base pair (bp) per generation means that replication of  $3 \times 10^9$  bps comprising the human genome leads to about 60 new single base mutations per individual.

**5.2.3 Transcription**

Only about 1–1.5% of the genome is reflected in the population of mature protein-coding transcripts. Protein-coding genes are transcribed from DNA into messenger RNA (mRNA) (see Figure 5-2). A single gene can give rise to multiple transcripts by means of alternative splicing and alternative sites of transcription initiation and termination, generating functional diversity. During transcription, the DNA duplex unwinds, and one of the strands serves as the template for synthesis of a complementary RNA strand. RNA is distinguished from DNA by the presence of uracil instead of thymine, ribose instead of deoxyribose, and a different three-dimensional folding pattern. The mRNA molecules are single stranded and function as the vehicle for translating genomic information into a protein.

In eukaryotes, genes are transcribed by one of the three different RNA polymerases (I, II and III, respectively). RNA polymerase I transcribes ribosomal RNAs (rRNAs) (except for 5S rRNA), RNA polymerase II transcribes mRNAs and micro RNAs (miRNAs), and RNA polymerase III transcribes 5S rRNA, transfer RNA (tRNA) and other small RNAs. In addition to RNA polymerase, initiation of gene transcription requires other proteins, so that multiple factors form the complex responsible for transcriptional initiation. This complex gets attached to the initiation site of transcription at the 5' end of the gene (the promoter) and determines which genes are transcribed in different cell types or during different developmental stages. The transcription factors (TFs), along with the activities of *cis*-acting enhancer and inhibitor sequences, also determine the level of gene expression. The enhancers and inhibitors can be located near the promoter of a gene, at the 5' or 3' side of the promoter or at significant distances away from the transcription start site. Such sequences are commonly found within first introns of many mammalian genes.

Most typically, only one of the two DNA strands gets transcribed, and the DNA strand that is similar to the transcribed mRNA sequence is referred to as the sense strand. The DNA sequence that serves as the transcriptional template is referred to as the antisense strand.

**5.2.4 Meiotic Recombination**

Meiotic recombination (1) refers to the reciprocal physical exchange of chromosomal DNA between the parental chromosomes and occurs at meiosis during spermatogenesis and oogenesis, serving to ensure proper chromosome segregation. During the four-strand stage of meiosis, two duplex DNA molecules (one from each parent) form a

hybrid, and a single strand of one duplex is paired with its complement from the other duplex. Single-stranded DNA is exchanged between the homologous chromosomes, and the process involves DNA strand breakage and resealing, resulting in the precise recombination and exchange of DNA sequences between the two homologous chromosomes. This process is highly efficient and does not usually result in mutations at the sites of recombination. Recombination thus shuffles genetic material between homologous chromosomes, generating much of the genetic diversity that characterizes differences between individuals, even within the same family.

The frequency of recombination between two loci along a chromosome is proportional to the physical distance between them, and historically, this provided the basis for defining the genetic distance between loci, allowing genetic maps to be constructed. The genetic proximity of two loci is measured by the percentage of recombination between them; a map distance of 1centimorgan (cM) indicates 1% recombination frequency between the two loci. The human genome sequence has made it possible to compare genetic and physical distances and to analyze variations in recombination frequency in different chromosomal regions. On average, 1 million base pairs (1Mb) correspond to 1cM (1% recombination frequency). However, there is a tremendous local variation between individual chromosomes and among particular chromosomal regions. For example, the average recombination rate is higher in the short arms of chromosomes and at the distal segments of the arms, but overall is suppressed near the centromeres. There is also a significant variation in the recombination rates between the sexes, with 1.6-fold more recombination on average in females relative to males. On average, female recombination is higher at the centromeres and male recombination at the telomeres (2).

### 5.2.5 Direction of DNA and RNA Synthesis

Each chromosome in the human cell consists of a continuous double-helical DNA strand; an average chromosome contains some 4–5 cm of DNA. The polarity of a single-stranded nucleic acid is defined by the position of the phosphodiester bonds, which connect the 3' hydroxyl group of one nucleoside to the 5' hydroxyl group of the next (see Figure 5-1). A nucleoside is composed of a purine or pyrimidine base and a deoxyribose (in DNA) or ribose (in RNA), and a nucleotide is composed of a nucleoside and one or more phosphate groups. The phosphate groups in a single nucleoside triphosphate are attached to the ribose or deoxyribose moiety via the 5' hydroxyl residue, and two of the three phosphates are removed during incorporation of each nucleoside triphosphate into DNA or RNA. When the new DNA strand is synthesized during replication or copied during transcription, the polymerase enzymes add new nucleotides to the 3' hydroxyl group of a growing polynucleotide chain. The new strand of DNA or RNA is thus

synthesized in the 5'–3' direction, and so the parental or template DNA strand is read in the 3'–5' direction. If two proteins are encoded by adjacent genes that lie on different strands along the chromosome, those genes are said to have opposite transcriptional orientations.

## 5.3 ORGANIZATION OF GENOMIC DNA

The 3 billion bps that constitute the human genome are packaged into 22 pairs of autosomes and the X and Y sex chromosomes. The chromosomal DNA can be divided into regions of heterochromatin and euchromatin: heterochromatin represents the “tightly” packed regions of chromosomal DNA and euchromatin represents the “loose” regions, which are generally the actively transcribed DNA regions. Using cytogenetic staining methods, differently packed chromosomal regions can be viewed as G (Giemsa staining)-bands, with the banding pattern characteristic of each individual chromosome providing the basis for the cytogenetic identification of each human chromosome. From early on, the dark G-bands were considered to reflect “gene-poor and GC-poor” regions, and the sequence of the human genome has proven this concept to be accurate. However, human genome sequence information has revealed that there can be a tremendous variation in the GC content across chromosomal regions.

Each of the 23 pairs of human chromosomes contains a single DNA duplex extending between the two telomeres. When the DNA in the human genome is stretched from one end to the other, its length would be more than 3 ft long! Remarkably, compacting the DNA by over 100,000-fold, which is required to fit the chromosomes

**FIGURE 5-3** Packaging of DNA into chromatin.

into the nucleus, is achieved by coiling and folding the double helix into a series of progressively shorter and thicker structures (Figure 5-3). Proteins that bind to DNA help direct and organize this folding, and the folded complex of DNA and protein is referred to as chromatin.

### 5.3.1 Nucleosomes and Higher Order Chromatin Structure

In addition to compacting the genetic material to fit into the nucleus, chromatin condensation can also regulate accessibility of the DNA for transcription and other processes. The simplest level of chromatin structure is the organization of DNA and histones into nucleosomes (3). Each nucleosome is a 147-bp long segment of DNA tightly wrapped almost two times around an octamer histone core. This octamer core contains two molecules each of the histones H2A, H2B, H3, and H4. Nucleosomes are the fundamental feature of all eukaryotic DNA and the sequences of the core histones are well conserved among even, distantly related species. A fifth histone, H1, binds to the DNA just outside each nucleosome and its sequence is less well conserved. A region of linker DNA, about 60bp in length in humans, usually separates adjacent nucleosomes, so that nucleosomes are for the most part regularly spaced.

Nucleosomes represent the first level in the packaging of naked DNA into chromatin and appear in the electron microscope as strings of 10-nm “beads.” The next level in packaging (see Figure 5-4) is the coiling of the nucleosomes, which, in some models, forms a solenoid that contains six nucleosomes per turn, measures

30nm in diameter, and is stabilized by interactions between H1 molecules bound to adjacent nucleosomes. Other models propose alternative patterns of nucleosomal stacking, with different internucleosomal interactions stabilizing the structure. Epigenetic modifications, primarily DNA methylation, and histone modifications also regulate the structure and dynamics of chromatin folding. Additional levels of folding can compress DNA into 300-nm fibers and a nearly 1000-nm metaphase chromatid.

### 5.3.2 Euchromatin and Heterochromatin

During metaphase, the entire chromosome is highly condensed but at other times, most chromatin is organized into fibers of intermediate diameter (30–300 nm), termed euchromatin. However, some portions of the genome remain highly condensed throughout the entire cell cycle, replicate late during S phase, and are termed heterochromatin. Many areas of heterochromatin are located close to chromosome centromeres and at the telomeres of acrocentric chromosomes, contain highly repetitive or simple-sequence DNA instead of genes, and may play a structural role in chromosome organization. A special form of heterochromatin is found in the inactive X chromosome in female cells, which contains genes but generally does not express them. This is partially due to a high degree of chromatin condensation and histone modification that does not allow access to the DNA by the transcriptional machinery. Inactive X heterochromatin remains highly condensed during the lifetime

FIGURE 5-4 Superhelical turns in DNA.

of somatic cells, but in germ cells, during oogenesis, it becomes active and euchromatic by the time of entrance into meiosis.

Formation of heterochromatin involves proteins that help direct condensation and packaging to achieve assembly of these proteins and DNA into heterochromatin. The molecular mechanisms behind heterochromatin formation have been revealed by studies of inactivation of the second X chromosome in female cells (4). Heterochromatin spreading is also thought to be involved in the initiation of X-chromosome inactivation that occurs in all female cells because condensation begins from a specific site on the X chromosome, the X-inactivation center, which in humans is located on Xq13. At this center, the X-inactivation-specific transcript (XIST) gene encodes a 17- to 19-kb long noncoding RNA, which is transcribed only from the inactive X chromosome and acts in *cis* to initiate X-inactivation. During early embryonic development, X-inactivation is random, and so females are mosaics with respect to whether the maternal or paternal X is active in each cell. Once established in somatic cells, the inactive X is stable through replication and cell division; i.e. the same inactive X will be inactive in all daughter cells.

XIST RNA inactivates genes at a significant distance from the gene that encodes it. Although XIST is essential for X-inactivation, regulatory genes including TSIX and a variety of TFs control XIST. While XIST is essential for the initiation of X-chromosome inactivation, it is not required for the maintenance of X-inactivation. The detailed analyses of the process of X-inactivation have informed more general aspects of heterochromatin formation and gene inactivation.

### 5.3.3 Centromeres and Telomeres

Special features of the DNA molecule that comprises each human chromosome are required at the centromeres and the telomeres. Located close to most centromeres are many copies of a 171-bp  $\alpha$ -satellite repeat that forms the core of the centromere. These sequences bind structural proteins that serve as a site for kinetochore formation and spindle attachment during metaphase. Certain alphoid repeats are found close to the centromeres of all chromosomes, while others are specific for one or a small number of chromosomes. The proteins and DNA sequences that make up the centromeres must also ensure that the two daughter chromatids are partitioned to different cells during cytokinesis (5).

As template-directed replication of DNA can only be performed in a 5'–3' direction, one strand of each duplex cannot be fully replicated at its 3' terminus by the DNA polymerase. Therefore, the telomeres of each human chromosome contain many copies of a short repeat 5'-TTAGGG-3', which can be replicated using the enzyme telomerase (6). This enzyme has an RNA component, which itself serves as a template and can elongate

the 5'-TTAGGG-3' repeat in a manner that does not depend on the DNA strand.

**5.3.3.1 Repeat Content of the Human Genome.** Less than 5% of the human genome sequence encodes proteins, whereas repeat sequences account for at least 50% of the sequence. The repeats fall into five categories: (i) transposon-derived repeats, often referred to as interspersed repeats; (ii) inactive retroposed copies of cellular genes (referred to as processed pseudogenes); (iii) segmental duplications consisting of blocks of around 10–300 kb that have been copied from one region of the genome into another; (iv) blocks of tandemly repeated sequences such as centromeres and ribosomal gene clusters; and (v) simple-sequence repeats consisting of direct repeats of short sequences such as (CA)<sub>n</sub> or (CGG)<sub>n</sub>, which have been extremely important for human genetic studies as they have been used as genetic markers (see “Interindividual Variations in the Human Genome”).

**Transposable elements** in humans, as in all mammals, fall into four types: long interspersed elements (LINEs), short interspersed elements (SINEs, including Alu sequences), long terminal repeat (LTR) retrotransposons, and DNA transposons. Both the number and age of transposable elements in the human genome are strikingly different from those in other species. The density of transposable elements is much higher in humans than in other species, and the human genome contains more ancient transposons than do other species. It thus appears that these repeats have survived because of a significant evolutionary advantage although their selective advantage and precise function are not well understood. Some chromosomes are extremely crowded with repeat elements (e.g. a 500-kb region on the short arm of the X chromosome has an overall transposable element density of 89%), whereas other chromosomal regions are nearly devoid of repeats (e.g. the homeobox gene clusters).

**Pseudogenes** are regions of DNA with many sequence elements of a potential transcriptional unit (e.g. promoter, protein-coding region, splice junctions, etc.), yet do not code for a functional product. They can originate after gene duplication when the duplicated sequence acquires a mutation that prevents its expression. For example, a member of the  $\alpha$ -globin gene family,  $\psi\zeta$ , has all the sequence characteristics of a functional globin gene, but the protein-coding region contains a point mutation that prevents the expression of a full-length globin (7). A second way in which pseudogenes originate is by the pathway of reverse transcription and integration. If the mRNA of a cellular gene is converted into complementary DNA by reverse transcriptase, a duplex DNA molecule can be formed that lacks introns and contains a poly(A) tract. Pseudogenes with this pattern are commonly found in genomic DNA, showing that cellular mRNAs are occasional substrates for reverse transcriptase and that the DNA products can integrate back into the genome.

**Large segmental duplications** (8) are especially enriched in pericentromeric and subtelomeric regions of chromosomes. These interchromosomal duplications are sequences from elsewhere in the genome, sized at 1–200 kb, and are much more common in humans than in yeast, flies or worms, suggesting a relatively recent origin for these genomic elements.

**5.3.3.2 Interindividual Variations in the Human Genome.** Sequencing of the human genome has exposed multiple interindividual variations. These variants include both simple-sequence repeat polymorphisms and single nucleotide polymorphisms (SNPs). Repeat polymorphisms can represent di- (mostly  $CA_n$ ), tri-, or tetranucleotide repeats, and they form the basis of the genetic map of the human genome. These repeat markers are multiallelic; the alleles differ in the number of repeat units and thus can be used to identify the maternal and paternal alleles of individuals as well as to define recombinations between marker loci. The high degree of length polymorphism among simple-sequence repeats within the human population is due to frequent slippage by DNA polymerase during replication. These repeats comprise about 3% of the human genome, and there is approximately one such repeat per 2 kb of genomic sequence. The large number and wide distribution of these repeats has facilitated mapping and identification of many genes associated with inherited human disorders solely based on their chromosomal position.

Certain specific triplet repeats can be unstable, expanding and contracting during meiosis and/or mitosis. If the repeat becomes excessively long, it can cause diseases such as Huntington disease or spinocerebellar ataxia, which both are caused by the expanded repeat CAG in the coding region of a gene and result in a long polyglutamine tract within the gene product. Some expanded repeats occur in 5'- and 3'-untranslated regions (UTRs) and also result in a disease due to an inhibitory effect on gene expression.

SNPs are also nonrandomly distributed in the human genome. Millions of SNPs have been identified in the genome sequence but only a small fraction are predicted to affect the protein sequence. This limits the extent to which such genetic variations contribute to the structural diversity of human polypeptides, but regulatory effects on gene expression may cause or result in susceptibility to a variety of human phenotypes.

Copy number variation (CNV) describes the variation identified within the population or associated with human diseases in genomic segments larger than the SNP and simple-sequence repeat polymorphisms but smaller than cytogenetically visible chromosomal abnormalities (9). An appreciation of the number and diversity of such variants has primarily been a product of comparative genomic hybridization studies in normal individuals (copy number polymorphisms) and in patients with a wide variety of genetic disorders. Although the number of sites that vary is small when

compared with the SNPs and simple-sequence repeat polymorphisms, the number of bps involved may be as much as two orders of magnitude greater (10). Similar to the SNP variations, CNVs may be associated with susceptibility to particular disorders or may be causative, especially when they arise *de novo* in an individual.

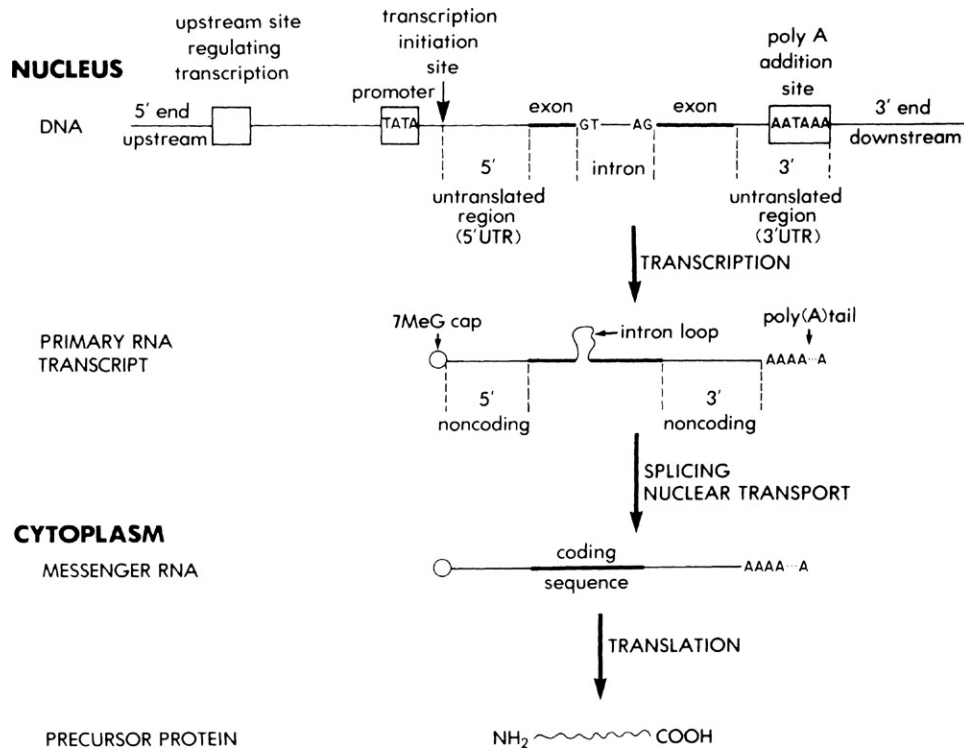

## 5.4 GENE STRUCTURE AND THE MOLECULAR PATHWAY OF GENE EXPRESSION

### 5.4.1 Structure of Transcriptional Units: Exons and mRNA

Sequences coding for a single eukaryotic mRNA molecule are typically separated by noncoding sequences into noncontiguous segments along the chromosomal DNA strand (Figure 5-5). The segments that are retained in the mature mRNA are referred to as exons. During transcription, the exons are spliced together from a larger precursor RNA that contains, in addition to the exons, interspersed noncoding segments referred to as introns. The number of exons coding for a single mRNA molecule depends on the gene and the organism, but ranges from 1 to more than 100. Human genes tend to have small exons, with a median value of only 123 bps. The exons are separated by introns, which can be less than 100 bp but can also exceed 10 kb. The size distribution of exons and introns of human genes based on the analyzed sequence information and comparison to worm and fly sequences are provided in Table 5-1.

Individual exons may correspond to structural and/or functional domains of the proteins for which they code, such as the signal peptide of secreted polypeptides or the heme-binding domain of globin. For some complex proteins, domains encoded by single exons often appear in apparently unrelated proteins, suggesting that the evolution of these proteins may have been facilitated by the ability to bring together different protein subdomains by exon shuffling. The origin of intron/exon structure is thought to be extremely ancient and to predate the divergence of eukaryotes and prokaryotes. However, prokaryotes and small eukaryotes (e.g. yeast) have lost their introns during evolution, perhaps because of the strong selective pressure on these organisms to retain a small genome size.

**5.4.1.1 Gene Expression.** The expression of individual genes can be regulated at multiple levels. Before a gene sequence gets translated into a polypeptide sequence, multiple events take place: activation of the local DNA structure, initiation and completion of transcription, processing of the primary transcript, transport of the mature transcript to the cytoplasm, and translation of the mRNA. All these steps can be the target of regulation and thus are potential control points for altering gene expression. Some genes are needed in all cell and tissue

types as they encode a crucial gene product. Such genes are often referred to as “housekeeping genes.” However, numerous human and mammalian genes show highly restricted cell- or tissue-specific expression patterns, and this spatial and/or temporal restriction of gene expression can also be regulated at multiple levels.

**5.4.1.2 Transcription.** Initiation of transcription happens when the compact DNA structure is loosened and short sequence elements in the 5' end of the gene guide and activate RNA polymerase (Figure 5-6). A group of such sequences is often clustered upstream of the transcription initiation site to form the promoter. The promoter is a region of DNA at the 5' end of the genes that bind RNA polymerase.

There are different types of promoters for RNA polymerases I, II, and III. RNA polymerases I and III are dedicated to transcribing genes encoding RNA molecules (rRNA and tRNA), which assist in the translation of the

polypeptide-coding genes. All RNA polymerases are large proteins and appear as aggregates consisting of 8–14 subunits. Significant amounts of information exist on promoter sequences specific for these polymerases. The basal apparatus, the generic minimal promoter sequence that is sufficient to initiate transcription of any protein-coding gene, contains an RNA polymerase II recognition signal as well as signals for general TFs needed for the binding of the polymerase by most genes. This minimal promoter contains a consensus sequence (5'-TATA-3', referred to as the TATA box), some 25 bp upstream of the site at which transcription begins, surrounded by GC-rich sequences, as well as the B recognition elements (BRE) sequence (TF recognition element), the Inr (initiator) sequence at the start site of transcription, and the DPE (downstream promoter element) at some 30 bp 3' from the transcription initiation site. Furthermore, some 50–200 bp upstream is the CAAT box, to which several TFs bind. The usual nomenclature of the numerous transcription factors is TF followed by a roman numeral to indicate the associated RNA polymerase. The general TFs, such as TFIIB, TFIID, TFIIIE, TFIIF, and TFIIF, facilitate the binding and activation of RNA polymerase II into an activated transcriptional complex.

Genes are constitutively expressed at some basal minimum rate determined by the core promoter. However, transcription can be increased or totally switched off by additional positive or negative elements (enhancers or silencers), which regulate the efficiency and specificity with which a promoter is recognized by the transcriptional apparatus. These *cis*-acting regulatory elements are typically short sequences located at some 200 bp

**FIGURE 5-6** A. Transcription of eukaryotic genes. B. Basic promoter elements in eukaryotes.

upstream from the promoter sequence but may also be placed at more distant locations. Finally, gene expression can be regulated by elements that respond to external stimuli. These response elements are often within 1000 bp upstream from the transcription start site. Genes under common control share similar response elements, recognized by regulatory TFs. Some response elements are extremely well characterized, such as heat shock response elements or glucocorticoid response elements.

Promoters do not necessarily have to lie upstream of the transcription initiation site. For example, most promoters for RNA polymerase III, including the 5S RNA promoter, lie downstream of the transcription start site within the coding sequence (11). This promoter binds the general transcription factor TFIID, a large protein with several zinc fingers, which then, along with the factors TFIIB and TFIIC, binds RNA polymerase III in a manner such that the polymerase is positioned at the exact spot where transcription begins. Although the mechanism of TFIID binding appears to be a common one, promoters that lie in exon sequences may be limited to the special situations in which multicopy genes such as 5S RNA or tRNA are subject to coordinate regulation.

Comparisons among many TFs have exposed some structural domains characteristic of the DNA-binding character of these proteins (Figure 5-7). These include zinc finger motifs, helix-turn-helix motifs, helix-loop-helix motifs, and leucine zipper motifs. The zinc finger motif binds a zinc ion with four highly conserved amino acids, two cysteines and two histidines ( $C_2H_2$ ) to form a finger-like loop (12). The typical loop is 25 amino acids long,

**FIGURE 5-7** Three-dimensional structure of DNA helix bound to TFs.

and the finger structure is often tandemly repeated. The helix-turn-helix motif is a common element of homeobox proteins. It consists of two short  $\alpha$ -helices separated by a short linker region and confers sequence specificity to DNA binding (13). The helix-loop-helix motif consists of two  $\alpha$ -helices separated by a loop that is flexible enough to allow two helices to pack against each other. The contact of the helix-loop-helix motif with DNA is considered to be looser than other TFs. The leucine zipper motif is a helical stretch of amino acids, with leucine at every

seventh amino acid position and occurring once in every two turns of the helix. Characteristic of most TFs is that they recognize and bind a short nucleotide sequence and their binding surfaces have extensive complementarity to the surface of the DNA double helix. Typically, eukaryotic TFs have two functional domains: a DNA-binding domain that binds to the DNA of the target gene and an activation domain that interacts with other proteins, which regulate transcription.

#### 5.4.1.3 Enhancers and *cis*-Acting Regulatory Elements.

Enhancers are defined as *cis*-acting sequences that increase transcriptional initiation but, unlike promoters, are not dependent on their orientation or their distance from the transcriptional start site (14). They may be found within the introns of the genes they regulate, within adjacent genes or, in extreme cases, an Mb or more away. Enhancer sequences are generally short, on the order of 20–30 bp, and bind specific TFs. When there is a mechanistic diversity in enhancer function, many enhancers facilitate the assembly of an activated transcriptional complex at the promoter via a chromatin looping mechanism. Other mechanisms involve recruitment of RNA polymerase II by enhancers or transcription of enhancer sequences to generate long noncoding RNAs that can facilitate transcription. Enhancers have roles in differentiation, tissue specification and tissue-selective gene expression, playing important roles during development and in specific cell types.

Silencers are another class of *cis*-acting regulatory elements that reduce transcription levels (15). They are less well characterized than enhancers, and some of them are position dependent while others seem to be position independent. They can bind TFs that act in transcriptional initiation, and many genes contain a combination of both positive and negative upstream regulatory elements that act in concert on a single promoter. This diversity of regulatory elements has the potential to precisely modulate gene expression with regard to cell type, developmental stage, and environmental conditions. Boundary elements are insulators, most of which block or isolate the effects of enhancers or silencers, limiting their action to the target genes.

Mutations of gene promoters or enhancers can alter the pattern of gene expression but not the structure of a particular gene product. While such mutations are much less frequent than structural mutations in genes, they provide insight into the elements of transcriptional regulation. For example, point mutations and partial deletions of the  $\beta$ -globin gene cluster that affect upstream regulatory sequences lead to reduced expression of adult  $\beta$  chains in  $\beta$ -thalassemia and/or increased expression of fetal  $\gamma$  chains in hereditary persistence of fetal hemoglobin (16).

### 5.4.2 Parts of a Gene that are Transcribed but not Translated

**5.4.2.1 5'-Untranslated Sequences.** Shortly after initiation of mRNA transcription, a 7-methylguanosine

residue is added to the 5' end of the primary transcript (see Figure 5-5). This 5' cap is a characteristic of nearly every mRNA molecule (17). Many functions have been ascribed to the cap, the most notable of which is protection of the mRNA from degradation by exonucleases. The cap may also promote splicing and nuclear export of the RNA and is recognized by the translational machinery. The 5'-UTR extends from the capping site to the beginning of the protein-coding sequence and can be several hundred base pairs in length. The 5'-UTR regions of most mRNAs contain a consensus sequence, 5'-CCA/GCCAUGG-3', known as a Kozak consensus sequence, involved in the initiation of protein synthesis. In addition, some 5'-UTRs contain upstream AUG codons that can affect the initiation of protein synthesis and thus could serve to control expression of selected genes at the translational level.

**5.4.2.2 Introns and Splice Junctions.** The number of introns in a simple transcriptional unit will be one less than the number of exons. More complicated arrangements exist in which an upstream exon can be spliced to any of several different downstream exons, or in which a complete transcriptional unit is nested inside an intron of a second transcriptional unit. In these situations, the same DNA sequence can be used as both exon and intron, depending on the transcriptional unit. Regardless of how the transcriptional unit is organized, the boundaries between potential exons and introns share common features that are important in the splicing process. Beginning from the upstream or 5' exon, these splice junctions have the sequence

```
...ag[GTaagt.....(>80 bp).....  
pyNpyPyPuApy...(~8–20 bp)..PyAG]...
```

where the brackets define the exon–intron junctions, the underlined nucleotides represent the splice donor, branch point and splice acceptor sequences, respectively, the upper case sequences are virtually invariant characteristics of every splice junction, and the lower case sequences are other conserved bases within the consensus splice sites. These conserved intron sequences serve a critical role in the splicing process, and many inherited diseases are caused by mutations of the consensus splice junctions. Most splicing mutations alter one of the invariant GT or AG nucleotides of the splice donor or splice acceptor (18) and result in abnormal splicing and either loss of the gene product or synthesis of an abnormal polypeptide chain.

A transcribed precursor RNA molecule must have its introns spliced out and its ends modified before export to the cytoplasm as mature mRNA. The spliceosome, which is composed of small nuclear ribonucleoproteins (snRNPs), mediates the splicing of the large number of pre-mRNA transcripts, collectively referred to as heterogeneous nuclear RNA (hnRNA). Spliceosomes are multienzyme complexes that both catalyze the splicing reaction and stabilize the intermediates in the splicing process. The snRNPs comprising the spliceosome consist of a set of five integral snRNA molecules (U1, U2, U4, U5, and U6) tightly associated with a large number of

proteins (19). RNA molecules in the snRNPs are among the most highly evolutionarily conserved sequences among eukaryotes. An initial intermediate of the splicing reaction is formed when the 5' guanylate end of an intron (the splice donor) is joined to an adenylate residue near the 3' end of the intron (the branch point) through a 2'–5' phosphodiester linkage (Figure 5-8). After the completion of exon–exon fusion, the excised intron is released as a “lariat structure” by cleavage at the splice acceptor.

The genes encoding rRNA and tRNA also contain exons and introns, but are spliced by different mechanisms than those required for mRNA splicing. Self-splicing of RNA without any protein factors is known to happen in prokaryotes, which suggests that introns have an extremely ancient evolutionary origin, predating not only the eukaryote/prokaryote divergence, but also perhaps the origin of proteins as well.

**5.4.2.3 3'-Untranslated Sequences and Transcriptional Termination.** The 3' ends of primary transcripts are determined by transcriptional termination signals located downstream of the ends of each coding region. However, the 3' ends of mature mRNA molecules are created by cleavage of each primary precursor RNA and the addition of a several hundred nucleotide polyadenylate (poly(A)) tails (see Figure 5-5). The cleavage site is marked by the sequence 5'-AAUAAA-3' located 15–20 nucleotides upstream of the poly(A) site and by additional GU-rich sequences 10–30 nucleotides downstream. Histone mRNAs, which do not have poly(A) tails, have stem-loop structures instead with cleavage of the primary transcript mediated by a distinct protein complex that includes the U7 snRNP (20).

Some complex transcriptional units contain several potential polyadenylation and/or transcription termination

**FIGURE 5-8** Splicing of mRNA.

sites. It is often difficult to distinguish the latter from the former as the product available for analysis (mRNA) has lost the portion of the 3' terminus originally transcribed by RNA polymerase. Alternative polyadenylation (or termination) sites can determine final protein structure if the longer precursor RNA contains an exon not found in the shorter precursor RNA. In a simple case, two proteins with different carboxyl termini are formed. But if alternative exon splice sites are made available in the longer precursor RNA, proteins with entirely different sequences can be produced.

The region from the translation termination codon to the poly(A) addition site may contain up to several hundred nucleotides of a 3'-UTR, which includes signals that affect mRNA processing and stability. Many mRNAs that are known to have a very short half-life contain AU-rich elements, 50–150bp sequences containing AUUUA motifs that regulate mRNA stability (21). Other, less well-characterized sequences can have similar effects. Removal or alteration of these sequences can prolong the half-life of mRNA, indicating that such elements represent a general regulatory feature of mRNAs whose level of expression can be rapidly altered.

### 5.4.3 Translation of RNA into Protein

**5.4.3.1 Genetic Code.** After intron sequences are spliced out of the primary RNA transcript and the 3' terminus is generated (in most cases, by the addition of a poly(A) tail), the mature mRNA is transported from the nucleus to the cytoplasm, where it is translated into a polypeptide chain. In the cytoplasm, tRNA molecules provide a bridge between mRNA and free amino acids (see Figure 5-2). Adjacent groups of three nucleotide sequences in the mRNA (codons) each bind to complementary three nucleotide sequences in tRNA (anticodons). Unlike most other nucleic acids, tRNA molecules have rigid tertiary structures. All tRNAs are L-shaped, with the anticodon located at one end and the amino acid binding site at the other end. Modified nucleotides, such as methylguanosine (mG) and pseudouridine ( $\psi$ ), are common in tRNA and help determine the specific three-dimensional characteristics of tRNA molecules. Aminoacyl tRNA synthetases specifically recognize different tRNAs and attach each tRNA to the correct amino acid. The last base in each codon is followed by the first base in the next, and thus the first codon in an mRNA molecule determines the reading frame for all subsequent codons.

The relationship between codon and amino acid sequence is referred to as the genetic code (Figure 5-9). Different tertiary structures of each tRNA are specifically recognized by the proper tRNA synthetase, ensuring the accuracy of the code. As the anticodon sequence itself does not determine tRNA tertiary structure, each amino acid may have several possible codons recognized by tRNAs with different anticodons but similar tertiary structures; that is, they are recognized by the same tRNA

FIGURE 5-9 The genetic code.

synthetase. For example, 5'-AAA-3' tRNA<sup>Phe</sup> (the tRNA coding for phenylalanine with the anticodon 5'-AAA-3') has the same tertiary structure and is charged by the same tRNA synthetase as 5'-GAA-3' tRNA<sup>Phe</sup>. Thus, both codons 5'-UUU-3' and 5'-UUC-3' code for phenylalanine using different tRNAs but the same tRNA synthetase. Additional redundancy in the genetic code arises because the third base in each codon–anticodon duplex (which is the first base from the 5' end of the anticodon) can be flexible according to the rules of Watson–Crick base pairing. In particular, G:U or U:G base pairs are often found in the third position of a codon–anticodon duplex, and the guanine analog inosine, found only in tRNA, can pair or wobble with A, C, or U in the codon. Despite the redundancy of the genetic code, synonymous codons are not used with equal frequency, and the pattern of codon usage (codon bias) may vary tremendously among different species and between nuclear and mitochondrial mRNAs.

The AUG codon, which codes for methionine, nearly always begins the protein-coding portion of each mRNA molecule. Therefore, the vast majority of newly synthesized peptides begin with methionine. The tRNA<sup>Met</sup> for the initiator AUG codon has a different tertiary structure from all other tRNAs, including the tRNA<sup>Met</sup> that functions in elongation. Translation of most mRNAs generally begins with the first AUG from the 5' end, which is typically embedded within a Kozak consensus sequence (5'-CCA/GCCAUGG-3') and establishes the reading frame (22). The UAA, UAG, and UGA codons are stop codons and have no cognate tRNAs. Thus recognition of any one of these codons by the protein synthesis machinery terminates the protein-coding portion of every mRNA molecule.

Mutations that change a codon into a different codon and would therefore encode a different amino acid result in a protein with an amino acid substitution, and these are described as missense mutations. However, the UAA, UAG, and UGA codons do not code for an amino acid but instead serve as a signal to terminate protein synthesis.

Mutations that produce one of these codons in the middle of a normal reading frame cause truncation of the newly synthesized protein during protein synthesis and are referred to as nonsense mutations. Frequently transcripts with a premature termination codon are degraded by a process called nonsense-mediated decay, so that no protein product is synthesized from the mutant allele, resulting in haploinsufficiency for the gene product.

**5.4.3.2 Protein Synthesis.** The biochemistry of protein synthesis (Figure 5-10) can be divided into the stages of

initiation, elongation, and termination. All three processes occur on ribosomes, cytoplasmic particles of protein and rRNA that align the different substrates of each reaction. When inactive, ribosomes exist as separate pools of the two ribosome subunits, described by their size or sedimentation coefficient (S value). The small 40S ribosomal subunit contains 18S rRNA and ~33 different proteins, and the large 60S subunit contains 28S rRNA, 5.8S rRNA, 5S rRNA, and ~50 different proteins. Beyond these structural components, there is a wealth of additional factors,

**FIGURE 5-10** Translation of mRNA into protein.

including both proteins and functional RNA molecules, that are required for ribosome biogenesis (23). Translation begins with the formation of a preinitiation complex that contains the 40S ribosomal subunit, initiator tRNA<sup>Met</sup>, GTP, and several protein initiation factors. An mRNA molecule initially binds to the preinitiation complex in conjunction with several initiation factors that interact with the 5' cap structure. The canonical model for identification of the AUG start codon involves scanning the mRNA in a 5'–3' direction until the consensus sequence 5'-CCA/GCCAUGG-3' is reached. However, internal ribosome entry sites (IRES) mediate ribosome recruitment and translational initiation for uncapped mRNA molecules and for translation when cap-dependent processes are inhibited (24). Binding of the 60S ribosomal subunit and dissociation of several initiation factors generate a complex of proteins and subcellular particles poised to begin synthesis of the first peptide bond.

A ribosome contains room for two tRNAs and their respective amino acids (see Figure 5-10). One tRNA at the peptidyl or P site is attached to the amino acid that has just been incorporated into a nascent peptide chain, and another tRNA at the aminoacyl or A site is attached to its cognate amino acid and is ready to participate in protein synthesis. During elongation, a peptide bond is formed between the two adjacent amino acids, the ribosome moves to the next codon in the mRNA, the tRNA at the P site dissociates from the nascent peptide chain, and the tRNA at the A site is translocated to the P site. This series of reactions is dependent on elongation factor 1 (EF1), which binds to free charged tRNAs, and EF2, which facilitates translocation from the A site to the P site. A single mRNA can be simultaneously translated by several active ribosomes, forming a polysome that can contain as many as 50 ribosomes.

When a codon signifying termination of protein synthesis (UAA, UAG, or UGA) is reached, the completed polypeptide separates from the tRNA at the P site, and the ribosome dissociates. In bacteria and yeast, a unique group of suppressor tRNA mutations is caused by

changes in an anticodon that then permit binding of a charged tRNA to a termination codon. Point mutations in an mRNA that would normally lead to premature termination codon (e.g. by changing a UUA codon into a UAA codon) are then partially suppressed by the mutant tRNA, allowing synthesis of a full-length protein with a missense change at the position of the mutant codon. The principle of suppression of nonsense codons, which represent about 30% of disease-causing mutations in humans, can be mimicked by treatment with aminoglycoside antibiotics and other pharmaceutical compounds (25). Used as a therapeutic approach, such treatment has the potential to affect therapy in a wide variety of genetic disorders.

**5.4.3.3 Protein Localization.** Gene products function in particular cellular compartments. For example, histones, tubulin, glycosyltransferases, peptide hormone receptors, and collagen are specifically localized to the nucleus, cytosol, Golgi apparatus, cell membrane, and extracellular space, respectively. Although many membranes contain pores large enough to accommodate a linear polypeptide chain, completely folded proteins are generally too large to fit through these pores. In addition to the problem of translocating soluble proteins across membranes, proteins that remain attached to the membrane must be placed and oriented in specific ways. These problems—protein sorting, translocation, and membrane orientation—have been solved by complex biochemical mechanisms that depend in part on short peptide sequences in each protein. One of the most well-understood pathways is the initial sorting of gene products into those that will remain inside the cytosol or nucleus and those that pass across the endoplasmic reticulum (ER) membrane, and which are then available for secretion into the extracellular space. This initial sorting is determined early in the translation of proteins destined to cross the ER by the presence of a specialized hydrophobic signal sequence of 20–30 amino acids (26) usually located at the N-terminus (Figure 5-11).

The signal sequence is first recognized when about 25 amino acids of the growing polypeptide have emerged

**FIGURE 5-11** Translocation of newly synthesized proteins across the endoplasmic reticulum.

from the ribosome and bind to a protein–RNA complex called the signal recognition particle (SRP). The SRP stops further translation until bound to a docking protein complex, the translocon, which is located on the surface of the ER and forms a hydrophilic membrane pore (27). The signal peptide passes through the pore, translation recommences, and the growing polypeptide crosses the membrane co-translationally. After the protein has passed into the lumen of the ER, signal peptidase, a protein on the luminal surface of the ER, cleaves the signal peptide to complete the initial phase of protein sorting.

Proteins extruded from the RER pass through the Golgi apparatus into secretory vesicles for transport to the cell surface. Proteins destined for the extracellular matrix are secreted from the cell when the vesicles fuse with the plasma membrane. Insertion and orientation of proteins destined for the cell membrane, however, require additional sequences that function either to stop transfer across the membrane (stop transfer sequences) or to initiate transfer of an internal loop of the nascent polypeptide chain (start transfer sequences). Start transfer sequences are recognized by SRP-like N-terminal signal sequences but are not cleaved from the protein after translocation. The number, order, and orientation of start transfer and stop transfer sequences determines the conformation of complex integral membrane proteins that span the membrane multiple times. Some soluble proteins that contain the short peptide sequence Lys–Asp–Glu–Leu (KDEL) remain in the lumen of the RER, such as binding protein (BiP) and protein disulfide isomerase (PDI). Both BiP and PDI facilitate the folding of newly synthesized proteins in the RER. PDI catalyzes the rearrangement of Cys–Cys disulfide bonds; BiP is a so-called chaperone that binds temporarily to portions of other proteins normally not exposed to the surface and, in doing so, prevents partially folded proteins from misfolding and/or aggregating. Soluble proteins destined for specialized compartments inside the cell, such as lysosomes or peroxisomes, use a signal sequence to gain access to the ER lumen but require additional mechanisms for proper subcellular localization. Lysosomal sorting depends on amino acid sequences that specify posttranslational addition of a mannose 6-phosphate residue. Proteins containing this modification are selectively transferred from the Golgi apparatus to the lysosomal interior. Failure to modify proteins destined for the lysosome in this way is responsible for the inherited disease mucopolipidosis II (I-cell disease).

There are over 1000 mitochondrial proteins, the great majority of which are encoded in the nucleus and synthesized in the cytosol. Similar to the proteins destined for the ER, transport of proteins across the mitochondrial membrane also depends on a signal sequence and utilizes several translocator complexes (28,29). The targeting sequence is usually located at the amino terminus and is cleaved upon import, but sometimes is internal to the protein and is therefore not cleaved. Unlike RER proteins, for which translation and translocation are

codependent, mitochondrial proteins are first translated completely, released into the cytosol, and then translocated into the mitochondrial membranes, intermembrane space or matrix. The potential problem of translocating a completely folded protein across a membrane pore is solved for mitochondria by complexes that include chaperone proteins of the Hsp70 family, which bind to proteins destined for the mitochondria and stabilize them in the unfolded state until after they have passed across the mitochondrial membrane, after which they assume their folded conformation.

**5.4.3.4 Posttranslational Modification.** Alterations to protein structure that occur after translation include the formation of disulfide bonds, hydroxylation, glycosylation, proteolytic cleavage, and phosphorylation. Phosphorylation of serine, tyrosine, and threonine residues is a common reversible modification that alters protein–protein interactions or controls enzymatic activity, mostly of intracellular proteins. The formation of disulfide bonds, hydroxylation, glycosylation, and proteolytic cleavage are generally not reversible and mostly involve extracellular proteins.

Intramolecular disulfide bond formation can begin co-translationally as the growing polypeptide chain enters the lumen of the ER. Some proteins, such as immunoglobulin light chains, have a sequential pattern of intra-chain disulfide bonds (e.g. between the first and second cysteines or third and fourth cysteines). Other proteins, such as proinsulin, have a more complicated pattern. Protein folding and establishment of the correct arrangement of disulfide bonds are critical steps in synthesizing a three-dimensional protein structure. Glycosylation of newly synthesized proteins may be O-linked via serine, threonine, or hydroxylysine residues, or N-linked via asparagine residues. O-linked glycosylation is catalyzed by glycosyltransferases located on the luminal surface of the Golgi apparatus. N-linked glycosylation begins with transfer of a 14-residue oligosaccharide from a lipid molecule (dolichol) embedded in the RER membrane to the asparagine residue of a growing polypeptide chain. At some sites, the oligosaccharide is highly modified by removal of some carbohydrates and addition of other carbohydrates to form a complex glycoprotein modification. Other sites are less modified and contain the original high mannose composition of the dolichol intermediate. Many glycoprotein modifications help determine the specificity of extracellular protein–protein interactions, such as antigen–antibody binding or attachment of cells to the extracellular matrix.

Proteoglycans are a specialized class of extensively glycosylated proteins that contain a protein core with long disaccharide chains branching off at regular intervals and can contain as much as 95% carbohydrate by weight. Proteoglycans are extremely hydrophilic and form hydrated gels that provide structural integrity to the extracellular space. During growth and development, extracellular remodeling is accompanied by endocytosis

and degradation of proteoglycans by lysosomal enzymes specific for different disaccharide chains; absence of these lysosomal enzymes produces mucopolysaccharidoses, such as Hunter syndrome or Hurler syndrome.

#### 5.4.4 Expression of Housekeeping and Tissue-Specific Genes

Many proteins that operate in basic metabolic functions such as energy generation or nutrient transport are found in all cells, and the genes that encode these proteins are described as housekeeping genes. They are characteristically expressed at a relatively constant level in all cells. More specialized genes that are not housekeeping are used only at specific times and places during development or in one or a limited set of tissues. The sequence of the human genome has revealed that the most common genes in our genome are those encoding TFs and nucleic acid binding proteins, which together encode 26.8% of the proteins with known or putative function. Other highly represented genes encode receptors, transferases, signaling molecules and transporters (30). These and other housekeeping genes usually account for 90% or more of the transcripts expressed in any particular cell type.

Analysis of genome sequence data has revealed that segments of DNA with a relatively large proportion of 5'-CpG-3' dinucleotide pairs and a very high GC content are frequently located near the 5' ends of all housekeeping and a proportion of tissue-selective genes (31). These CpG islands thus mark promoters and are present adjacent to about 70% of annotated genes, accounting for about half of the known CpG islands. Some of the remaining CpG islands have been associated with transcriptional activity, suggesting that these sequences mark the promoters of unknown transcripts and genes. On average, CpG islands are about 1000-bp long and most are less than 2000 bp in length. The CpG sequences within each island are generally unmethylated and are thought to facilitate transcription either by preferential binding of TFs or by altering chromatin structure to a nucleosome-deficient and transcriptionally permissive state. Methylation of CpG islands is associated with reduced transcriptional activity, such as on the inactive X chromosome, although the methylation event appears to follow rather than initiate transcriptional silencing.

**5.4.4.1 Gene Families.** Gene families consist of structurally (and usually functionally) related genes with a common evolutionary origin. Multiple levels of hierarchical subfamily structure are common. Examples include the immunoglobulin variable region ( $\kappa$  and  $\lambda$ ), collagen (interstitial and basement membrane), and globin ( $\alpha$  and  $\beta$ ) gene families. Some gene family members, such as collagens, are dispersed among different chromosomal locations, but many others, such as the  $\kappa$  or  $\lambda$  variable region genes, are physically linked. Among gene families that exhibit linkage, members are usually oriented in the same direction. In some cases, linkage is thought to be an evolutionary

footprint without functional significance, suggesting that evolutionary divergence of the gene family occurred through successive rounds of duplication in tandem arrays. However, in other gene families, such as the immunoglobulins, linkage has been conserved during evolution because it provides a mechanism for coordinated or regulated control of gene expression. Even when dispersed, coordinated expression of members of gene families can be regulated by similar control mechanisms by carrying similar response elements in their 5' regulatory regions.

### 6.1 INTRODUCTION

Despite the tremendous advances in human genetics enabled by the original public and private human genome projects and brought to fruition with high-throughput genotyping and “Nextgen” DNA sequencing, many aspects of human biology still cannot be adequately explained by nucleotide sequences alone. Normal human development requires the specification of a multitude of cell types/organs that depend on transcriptional regulation programmed by epigenetic mechanisms. Epigenetics refers to modifications to DNA and its associated proteins that define the distinct gene-expression profiles for individual cell types at specific developmental stages. Disruption of such control mechanisms is associated with a variety of diseases with behavioral, endocrine, or neurologic manifestations, and quite strikingly with disorders of tissue growth, including cancer. While the involvement of epigenetic alterations in many of these diseases has been known to specialists for some time, the importance of epigenetics in clinical medicine has only just begun to emerge. Current research is focused on characterizing *cis*- and *trans*-acting influences of the genetic background on epigenetic marks, delineating cell type or tissue-specific epigenetic marks in human health and disease, studying the interaction between epigenetic marks and the environment especially with respect to fetal programming and risks for common adult onset disorders, and modulating adverse epigenetic states by drug-based and nutritional therapies.

### 6.2 EPIGENETIC MECHANISMS: CHROMATIN, DNA METHYLATION AND LONG NONCODING RNAs

An epigenetic trait is defined as a “stably heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence” (1). Epigenetic patterns, essential for controlling gene expression in normal growth and development, are established by a number of mechanisms including DNA methylation at cytosine residues in CpG dinucleotides and covalent modifications of histone proteins, as well as by less well-understood mechanisms controlling long-range chromatin architecture within the cell nucleus.

DNA in most eukaryotic cells is packaged with histone proteins to form nucleosomes—the beads in the well-known “beads-on-a-string” structure of chromatin. Most double-helical DNA is wrapped around an octamer core of four histone homodimers, H2A, H2B, H3, and H4, which through multiple levels of packaging establish chromatin conformations that can be relaxed or tightened to either facilitate or repress transcription in specific cells at critical times in development. Condensed states of chromatin (heterochromatin) inhibit transcription, while relaxed states (euchromatin) are conducive to transcription. For instance, non-transcribed telomeric and centromeric repeat regions are often silenced due to their compact heterochromatin environment, while highly active genes, usually located within euchromatin, are often expressed due to a more open chromatin environment, often with a short nucleosome-free segment of DNA

**FIGURE 6-1** Epigenetic organization of chromatin: Layering of DNA methylation, histone modification to control gene expression. DNA of a gene promoter can be unmethylated (white circles) and in most cases the gene is expressed or the promoter can be methylated (blue circles) and in most cases the gene is not expressed. DNA is not independent of its associated histone proteins. Histone modifications are established and maintained independently or dependently on the DNA methylation state of a region. These protein modifications can activate (open orange circles) or repress (filled orange circles) gene transcription. Although not shown in this figure, but mentioned in the text, additional epigenetic processes, including microRNA and long noncoding RNAs, also contribute to gene regulation. The DNA/histone protein nucleosome core is further compacted to form higher-order chromatin structures that also contribute to gene regulation.

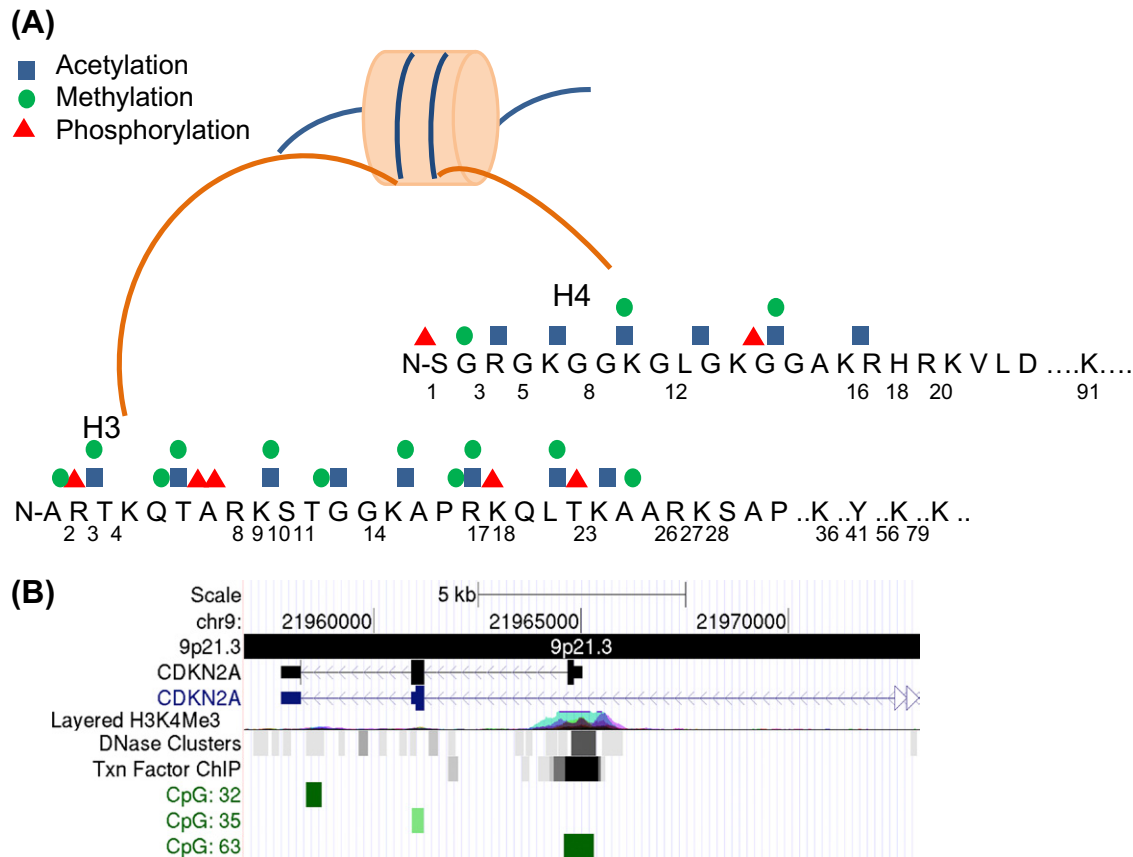

near the transcriptional start site. Further regulation is accomplished by assembling promoter–enhancer complexes via long-range chromatin looping (2), a process that is regulated by specific DNA sequences called insulators, which are often located at the points of intra-chromosomal contacts from which the loops emanate.

The core histones are subject to diverse posttranslational modifications, including methylation and acetylation, often at lysine and arginine amino acid residues in the loosely structured N-terminal histone tails that project from the tightly structured nucleosome cores (Figure 6-1). Depending on their pattern of modifications, these N-terminal histone tails are recognized by other chromatin proteins that activate or repress transcription, and therefore certain histone modifications can establish, and potentially maintain, active or silent epigenetic states (Figure 6-2). The cellular enzymes that catalyze histone modifications are therefore important modifiers of gene expression. Mutations in some of these genes can lead to human disease, which will be discussed in detail in later sections of this chapter. Examples include histone acetyltransferases (HATs), histone deacetylases (HDACs), histone methyltransferases, and histone kinases. The modifications catalyzed by this large array of enzymes can be sequential and interdependent, mutually exclusive, or independent. Despite this complexity, data from individual labs and

large-scale mapping projects such as ENCODE are starting to reveal some general rules for the histone code, with a finite number of specific combinations of histone modifications correlating with genes that are expressed, repressed, or poised for expression but not yet expressed (3,4).

DNA methylation involves the transfer of a methyl group to cytosine in a CpG dinucleotide, catalyzed by DNA methyltransferase enzymes that establish and maintain these patterns through cell division. Importantly, DNMT1, the major maintenance methylase, has a high affinity for hemimethylated DNA (5) and it therefore acts to propagate the original methylation patterns. One stage-specific isoform of DNMT1, DNMT1O, is an oocyte-derived protein that enters cell nuclei only at the eight-cell stage of the early embryo, and has an essential role in the maintenance of epigenetic marks (6).

Independent of maintenance methylation, methyl groups must also be added *de novo* at various times during development; for example, to establish parental imprints on the DNA (7), to methylate centromeric DNA and other constitutive heterochromatin, and to defend the host against foreign DNA integration and expression. The DNMT3 family includes two *de novo* DNA methyltransferases: DNMT3A and DNMT3B. These enzymes can efficiently methylate CpGs that are not in hemimethylated DNA. Another member of the DNMT3

**FIGURE 6-2** (A) Histone modifications of histone H3 and H4 N-terminal tails. Posttranslational modifications of N-terminal tails (these can also occur in the C-terminal domain, but are not shown here) can occur in combination and are read by the appropriate protein to establish local and global decondensed or open and condensed or closed chromatin states: Ac, acetylation (blue squares); Me, methylation (green circles); and P, phosphorylation (red triangles). (B) Snapshot from UCSC genome browser representing H3K4 methylation in the promoter of the tumor-suppressor gene CDKN2A. This diagram is an example of epigenetic data available in UCSC genome browser. The description of each genomic feature is shown on the left. Two isoforms of CDKN2A are shown in black and blue, here we focus on a shorter (black) isoform. Enrichment for active histone H3K4me3 is shown by multiple colors in 9 cell lines. The peak of H3K4me3 coincides with transcription start site of CDKN2A, CpG island (green), as well transcription-factor-binding sites (TxN factor ChIP) and DNase clusters, which are indicators of open chromatin. All of these marks—H3K4me3, transcription-factor binding as well DNase clusters—indicate that CDKN2A is active transcribed in these cell lines. Information about other histone marks and DNA methylation levels is available from the UCSC genome browser under multiple tracks from the Regulation section. (This image was downloaded from UCSC genome browser <<http://genome.ucsc.edu/>> (Ref. (313)). The ENCODE Regulation data is from Ref. (314).

family—DNMT3L—has no catalytic activity, but can bind to and activate DNMT3A and is required to maintain allele-specific methylation in imprinted regions of the genome (8). The function of DNMT2 appears to be primarily in RNA methylation (9).

In mammalian cells, DNA methylation occurs predominantly on cytosines located in CpG dinucleotides within repetitive elements and in some non-repetitive sequences in intergenic and intragenic regions, while CpG methylation is usually excluded from gene promoter regions that are especially CpG-rich, referred to as CpG islands (10). In 98% of the genome, CpG dinucleotides appear at a low frequency of 1/80 nucleotides, but in the remaining 2% of the genome they are found in CpG islands of from 200 bp to several kb in length, with a much higher CpG density. Approximately 50–60% of genes contain CpG islands, typically though not always in their proximal promoters. Such CpG islands are almost always

unmethylated in normal tissues, with the exception of imprinted genes, X-inactivated genes, retrotransposons, and a few genes with tissue-specific silencing (11,12). DNA methylation at CpG island-associated promoters usually causes gene silencing, either by directly interacting with transcription factors or by recruiting methyl-binding proteins that then recruit histone-modifying enzymes to transform chromatin to a repressive state (13). Importantly, the general protection of CpG islands from methylation can break down in pathological conditions, particularly in cancer cells, leading to aberrant gene silencing (14).

Although DNA methylation and histone modifications are regulated by different sets of enzymes, crosstalk among these modifications occurs through interactions of enzymes and other proteins that create and recognize these patterns (15). The relationship between these two central types of epigenetic modifications is known to

be bi-directional, with histone marks being more labile and DNA methylation more stable (15–20). Thus DNA methylation can act to “lock in” epigenetic states. However, regulating metastable states of gene expression is so crucial in development and tissue homeostasis that other mechanisms, in addition to histone modifications and DNA methylation, come into play to establish and maintain epigenetic states. Regulatory noncoding RNAs, including small interfering RNA (siRNA), microRNAs (miRNAs), and long noncoding RNAs (lncRNAs) play important roles in the regulation of gene expression at several levels of transcription, mRNA degradation, splicing, transport and translation (21). The main function of siRNAs and miRNAs is posttranscriptional regulation. They pair with homologous mRNAs and may cause translational repression or more generally degradation (21). In addition, both types of small RNA molecules are implicated in transcriptional gene regulation through modification of epigenetic marks. Though more research is required, preliminary data suggest that this miRNA-mediated transcriptional regulation is coupled with other epigenetic regulatory mechanisms as well. The *POLR3D* gene has been shown to be silenced in *cis* by the miRNA mir-320, encoded within the *POLR3D* locus, through recruitment of the H3K27 methyltransferase EZH2 (22).

lncRNAs are found at various locations in relation to protein-coding genes. They may be antisense, intronic, intergenic, promoter or enhancer associated and can regulate transcription both in *cis* and *trans* by a number of different mechanisms (23). Specifically, lncRNAs have been shown to establish specialized nuclear compartments devoid of RNA-polymerase II. Chromatin-associated polycomb repressive complexes mediating epigenetic changes are found in these nuclear compartments (21,23), as exemplified by the *XIST* lncRNA that is essential for initiating X-chromosome silencing (24). lncRNAs are also found in imprinted gene clusters where the expression of monoallelically expressed lncRNAs results in spreading of repressive chromatin marks such as DNA methylation, H3K27, and H3K9 methylation in *cis* for distances up to 1kb (25). The functions of lncRNAs seem to be quite diverse; in contrast to the in *cis* silencing mediated by *XIST* and imprinted lncRNAs, non-imprinted lncRNA *HOTAIR* expressed from the *HOXC* gene was shown to recruit polycomb repressive complex2 and histone demethylase LSD1 resulting in acquisition in *trans* of silencing histone marks at genes within the *HOXD* gene cluster located on another chromosome (26). In spite of different details in their functions, it has been estimated that 20% of lncRNA expressed in human cells is bound by polycomb group proteins, suggesting a shared biochemical mechanism for their role in epigenetic silencing (27).

In addition to 5-methylcytosine (5mC), mammalian DNA contains a related modified base—5-hydroxymethylcytosine (5hmC). Both of these modifications have been known for decades, but have received very different

levels of attention in the scientific literature. 5mC has been studied extensively, and its role as an epigenetic modification involved in gene regulation, X-chromosome inactivation (XCI), genomic imprinting, silencing of transposons, and cancer development is well described. On the other hand, 5hmC has only recently entered center stage when it was shown that proteins in the ten-eleven translocation (TET) family of oxygenases catalyze the conversion of 5mC to 5hmC, and that the gene for one of these enzymes, *TET2*, is sometimes mutated in human cancers, notably in cases of acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS). The formation of 5hmC can in principle lead to demethylation of DNA, either by a passive process (failure of remethylation of these sites in S-phase) or by an active mechanism (direct demethylation of 5hmC or base excision of a further modified product such as carboxy-mC), so it has been suggested that TET family oxidases probably contribute to the dynamics of DNA methylation. 5hmC has been found in many cell types and tissues, with particularly high levels in the brain and in embryonic stem (ES) cells. As discussed in the next section on epigenetic reprogramming, TET1 has been shown to be important for self-renewal and maintenance of ES cells.

### 6.3 EPIGENETIC REPROGRAMMING

Patterns of DNA methylation differ extensively between the sperm and the egg, and cytosine methylation in DNA is dynamically reprogrammed both during germ cell and early embryonic development. This process has been well studied at the whole genome level and for specific imprinted genes, leading to the conclusion that most areas of the diploid genome become equalized in their epigenetic marks on the paternal and maternal alleles by the time early preimplantation development is completed, with strong allelic asymmetries persisting mainly at imprinted loci (28) and at certain other loci with haplotype-dependent allele-specific methylation. This equalization of the two alleles at most autosomal loci, which is essential for classical Mendelian transmission of human genetic disorders, involves early post-zygotic reductions in DNA methylation, which seem to result both from active demethylation, via a mechanism that is still being researched, and passive demethylation, in which CpG methylation is diluted through early rounds of DNA replication in the presence of relatively low-maintenance methylase activity.

Genomic levels of the “sixth base” 5hmC also change during development, probably as a function of the activity of TET family enzymes, which are particularly highly expressed in ES cells (29–31). In the mouse genome, 5hmC was shown to be widely distributed throughout non-repetitive regions, whereas satellite repeats (which are located in heterochromatin) are highly enriched for 5mC but substantially less for 5hmC (32). Distinct 5hmC and 5mC patterns are observed at CpG islands overlapping

with gene promoters, whereas 5 mC is depleted from these regions, and 5 hmC is well represented. Interestingly, the presence of 5 hmC and depletion of 5 mC at CGI promoters is associated with increased transcription in ES cells (32). Consistent with these observations, active histone marks H3K4me3 are enriched in promoters with high 5 hmC, suggesting that enriched 5 hmC at CGI promoters is positively correlated with active transcription. Decline of TET oxidase levels during differentiation of ES cells is accompanied by reduced promoter 5 hmC and increased 5 mC levels correlating with silencing of certain key developmental regulatory genes (32,33). Thus, one current hypothesis is that hydroxymethylation and the TET proteins could play a role in erasing methylation marks from promoters of pluripotency-related genes during differentiation (32,34). Hydroxymethylation may also play a role in epigenetic reprogramming of primordial germ cells (paternal genome) and early embryos (35,36).

## 6.4 EPIGENETIC REGULATION OF X INACTIVATION

Inactivation of one of the two X chromosomes in female cells was first described by Mary Lyon in 1961 (37) and since then remains the outstanding example of epigenetic silencing of nearly an entire chromosome, which is regulated in *cis* by a small control region in the DNA of this chromosome known as the X inactivation center (XIC). XCI has evolved in placental mammals to achieve dosage compensation of X-linked genes between female cells with two X chromosomes and male cells carrying only one X and one (small and rudimentary) Y chromosome. It is hypothesized that the X and Y chromosomes have evolved from a pair of autosomes, coinciding in time with the evolution of the placenta and driven by the acquisition of the sex determining region Y (*SRY*) gene. In the course of mammalian evolution, the *SRY*-carrying Y chromosome has been significantly reduced in size and lost most of its active genes, retaining in addition to *SRY* a few other genes playing a role in male reproduction, whereas the X chromosome has acquired additional genetic material through translocations from autosomes. This scenario resulted in homology between the X and Y chromosomes being reduced to two small pseudo-autosomal regions (PAR1 and PAR2) (reviewed in (38,39)). It is estimated that the human Y chromosome contains ~45 expressed genes, whereas the X chromosome has ~1300 known genes (38,40). The resulting major bias in copy number for X-linked genes between males and females is mostly transcriptionally compensated via XCI.

X-chromosome deletion and translocation mapping in mouse and humans defined a critical region for the XIC covering ~1Mb and mapping to chromosome band Xq13 in humans (41,42). Further discovery within this region of a lncRNA, the X-inactive specific transcript *XIST*, which is expressed from the XIC at high levels only on the X chromosome destined for inactivation, and which

quickly spreads to coat the entire inactive X in female cells, was a major breakthrough in understanding the mechanism of XCI (43–45). The majority of the work on mechanisms of X inactivation was done using mouse preimplantation embryos and ES cells. Before turning to the details of this mechanism, as useful as mouse models have been in unraveling XCI, there are a number of substantial differences in the XCI process between mice and humans. In mice, there are two waves of XCI; the first is imprinted inactivation of the paternal X, which is initiated shortly after fertilization. This pattern of paternal X-chromosome silencing is maintained in extra-embryonic tissues, but is erased and reestablished in a random manner in the inner cell mass (ICM) of blastocysts, that gives rise to the embryo proper (46). In contrast, in human embryos XCI is initiated at the blastocyst stage and is random in both ICM and trophoblast (47).

Random XCI is a multi-step process that can be divided into three steps: initiation, spreading, and maintenance. Initiation involves counting the number of X chromosomes per cell so that one X remains active per diploid number of autosomes. In other words, XY males and XO females keep their single X chromosome active, whereas XX, XXX, and XXXX females and XXY males inactivate all but one X, up-regulating *XIST* RNA on all of the X chromosomes destined to become inactive. The spreading of inactivation is achieved through sequential acquisition of epigenetic marks starting with *XIST* RNA, followed by polycomb repressor complex2 recruitment, shift to late replication timing, enrichment of histone macro H2A, silencing of chromatin marks such as histone H3 and H4 hypoacetylation, H3 Lysine27 methylation, and finally DNA methylation of CpG-rich promoters (48,49). Once established early in embryonic development, the inactive state of an X chromosome is maintained through somatic cell divisions utilizing epigenetic modifications of DNA and histones (50).

Regulation of *Xist/XIST* expression itself is a complex process involving multiple *cis*- and *trans*-acting factors. In mice, pluripotency transcription factors Oct4 and Nanog are negative regulators of *Xist* expression, such that a decrease in their expression early in post-zygotic development coincides with cell differentiation, upregulation of *Xist*, and the onset of XCI (51–53). Several sub-regions within the mouse Xic are involved in *Xist* regulation: *Tsix*—an antisense transcript of *Xist*—is a negative regulator of its expression and it protects the active X from inactivation (54,55); noncoding RNA *Jpx* (56), X-pairing region (Xpr) (57,58), and protein-coding *Rnf12* (59,60) are positive regulators of *Xist* expression. There are a number of differences in the organization of the mouse and human XIC/Xic, and there is little sequence conservation between mouse and humans (42,61). Based on comparative analysis of Xic in several mammalian species, it seems that Xic is an evolutionary labile locus and the orthologues across different mammalian species act via multiple diverse strategies (47).

For example, in mouse *Jpx* is located 9kb upstream of *Xist*, whereas in humans it is separated by 90kb (42,61). Furthermore, human *TSIX* shows little conservation with mouse, and is not transcribed through the entire *Xist* as in mouse (62). Also, in human fetal cells *XIST* and *TSIX* are co-expressed from the inactive X (63), suggesting that *TSIX*-mediated downregulation of *XIST* might be nonfunctional in humans.

More research is required to understand the regulation of XCI in human embryonic development. Despite the elegant picture that has emerged, some steps of the XCI process are still not completely understood. A lot of intriguing questions remain, such as how the cell counts the number of Xs and decides how many to inactivate; how X chromosomes communicate between each other in order to retain one active X and to avoid a lethal state with two active or inactive X chromosomes; how *XIST* RNA recruits repressive chromatin markings; and how spreading of the inactivated state occurs along the inactive X chromosome. These are active areas of current research (46,64).

#### 6.4.1 Special Aspects of X Inactivation Relevant to Human Genetic Diseases

Not all X-linked genes are subject to X inactivation; some genes are robustly expressed from both Xa and Xi. It is estimated that 3% and 15% of genes escape XCI in mouse and humans, respectively (65). Again, there are fundamental differences between human and mouse genes that escape X inactivation. Mouse genes escaping X inactivation are randomly distributed along X, whereas in humans they tend to cluster together. Only six of such genes overlap between mouse and humans (42). Expression analysis of ~600 X-linked genes in human fibroblasts with nonrandom X inactivation and in rodent-human hybrid cells carrying an inactive human X have shown that ~15% of the X-linked gene escape X inactivation; ~10% of genes show heterogeneous escape status among different individuals. Genes that escape XCI are frequently expressed at lower levels from Xi than from Xa (66). Further, based on DNA methylation analysis of X-linked promoters, it is estimated that 12% of the X-linked genes show variable inactivation status among different somatic tissues (67). Most but not all genes that escape XCI have Y-linked homologs either within or outside of PAR regions, some are functional whereas others are pseudogenes. On the human X chromosome, the location of genes that escape XCI is seemingly not random, as the majority of the genes are clustered within regions of X which have the highest degree of homology to the Y chromosome (66).

Genes that escape XCI are important potential contributors to phenotypes of X-chromosome aneuploidy, both in the relatively common situation of X-chromosome deficiency (females with Turner syndrome, karyotype 45,X; often abbreviated XO) and in

supernumery X-chromosome syndromes. Less than 1% of XO conceptuses survive to birth (68), with surviving individuals having a female phenotype and manifesting Turner syndrome—namely short stature, ovarian dysfunction, and a variety of somatic abnormalities such as webbed neck, high arched palate, increased carrying angle of elbows, aortic coarctation, renal malformations, and cognitive problems with visual-spatial perception, and social interactions (69). These problems are presumed to be due to haploinsufficiency of the few genes that normally escape X inactivation (i.e. are present in two active copies in normal XX females). Most of these genes are in the PARs: one of the genes within PAR1, *SHOX*, has been implicated in the short-stature phenotype of females with Turner syndrome, and short stature is observed in individuals with sub-chromosomal deletions encompassing PAR1 on either the X or Y chromosomes (70). Individuals carrying supernumerary X chromosomes—XXX and XXY—have increased mortality rates, possibly resulting from overexpression of X-linked genes that escape XCI (42).

Interestingly, the human X chromosome is enriched for genes expressed in brain, with more than 80 such genes identified to date (71,72). Thus, many X-linked conditions present clinically as syndromic or non-syndromic ID. Sex-chromosome dimorphism makes the inheritance of X-chromosome conditions more complex than patterns observed for autosomal dominant or recessive inheritance. The majority of X-linked disorders affect males, with carrier females either being unaffected or mildly affected, depending on whether there is skewed or random XCI in critical tissues and its impact on the phenotype. Normally, XCI is random, resulting in cellular mosaicism, with two approximately equal populations of cells that express either paternal or maternal X. However, there are cases of significant skewing of X inactivation. Rare mutations within XIC may result in failure to inactivate the X that carries these mutations, with preferential inactivation of the other X chromosome. This type of skewing occurs at the onset of XCI and is termed “primary skewing” (73). Less rare is a mechanism that confers a selective advantage for cells with one of the active Xs, resulting in “secondary skewing.” This situation frequently occurs when part of an X chromosome is deleted (42). Usually skewed XCI selection favors cells with a normal active X, selectively silencing the mutation-bearing X chromosome (74). However, there are rare examples of preferential activation of a mutant X chromosome in female carriers, resulting in more severe disease phenotype, such as rare cases of Duchenne muscular dystrophy in females (75), adrenoleukodystrophy caused by *ABCD1* mutation (76), or Xp11.22–23 duplication in females with ID, speech delay, and autism (77,78). These situations can result from stochastic factors, presence of a genetic mutation or autosomal translocation on another X, or faster proliferation of cells carrying the mutation on the active

X (74). There are two known exceptional situations in which females carriers of X-linked mutations are more severely affected than males: mutations in the *ephrin-B1* gene (79) and *EFMR* (80).

Another example of females affected by an X-linked disorder is the severe neurodevelopmental disorder Rett syndrome, caused by heterozygous mutations of the X-linked *MECP2* gene. *MECP2* mutations are extremely rare in XY males, either because of early embryonic lethality or due to the fact that sporadic *MECP2* mutations almost exclusively occur on the X-chromosome transmitted from fathers to daughters, possibly secondary to deleterious effects of *MECP2* mutation on the oocyte (81). In classical Rett syndrome patients, X inactivation is generally not skewed in brain tissue of affected girls (82), but skewed XCI has been reported in females with very mild symptoms of Rett syndrome (83,84).

For all these reasons, when counseling families with suspected or known X-linked conditions, knowledge of the inactivation status of the gene, as well as the presence of XCI skewing are important factors. Testing for skewing of X inactivation based on DNA methylation analysis of a polymorphic CAG repeat within exon1 of the *AR* gene (85) is routinely used in molecular diagnostic laboratories to address this question. However, it should be kept in mind that usually this test is performed on clinically accessible tissues, such as blood or buccal swabs, and the degree of skewing might vary among different tissues (74).

## 6.5 GENOMIC IMPRINTING

Genomic or parental imprinting was discovered some 30 years ago, but the phenomenon of parent of origin-specific inheritance was observed 3 millennia ago when mule breeders found that mating a female horse to a male donkey gave rise to a “mule” whereas the reciprocal cross yields a phenotypically distinct equine, called a “hinny” (86). Thus, in violation of classical Mendelian principles, two animals with exactly the same diploid genome can be phenotypically distinct depending only on the parental origins of each haploid chromosome complement. This phenomenon can now be explained by epigenetics. The first embryological evidence of genomic imprinting came from experiments done in the mid-1980s in which attempts to reconstitute a viable mouse embryo entirely from either the maternal germline (gynogenetic conceptus derived from the fusion of two female pronuclei) or the paternal germline (androgenetic conceptus from two male pronuclei) were uniformly unsuccessful (87,88). From these results, the investigators immediately postulated that the maternally transmitted and paternally transmitted genomes (really epigenomes) were not functionally equivalent. Subsequent results analyzing mouse transgenes suggested that different DNA methylation on maternal vs. paternal alleles might be an important mechanism accounting for this nonequivalence.

Imprinting has turned out to affect a relatively small, but important subset of mammalian genes. The first endogenous imprinted genes, including the maternally expressed mannose-6-phosphate/insulin-like growth factor 2 receptor (*Igf2r*) gene, the paternally expressed insulin-like growth factor 2 (*Igf2*) gene, and the maternally expressed non-translated *H19* RNA, were discovered and studied in the early 1990s, first in mice and quickly thereafter in humans. Imprinting tends to be well conserved between the two species, but there are some exceptions in which specific genes, for example, *Igf2r*, are functionally imprinted in mice but not in humans. Recently updated catalogs of imprinted genes in human and mouse (<http://www.geneimprint.com>, <http://www.otago.ac.nz/IGC> and <http://www.mgu.har.mrc.ac.uk/imprinting/imprinting.html>) show >100 imprinted transcripts with ~63 strongly imprinted genes documented in humans (Figure 6-3). Many of these imprinted genes play vital roles in embryonic growth, neonatal behavior, or both, and these genes sometimes exhibit tissue or developmental stage-specific monoallelic expression patterns (89). This parent-specific expression of imprinted genes imposes a functionally haploid state at imprinted loci in normal tissues, and hence deleterious effects from heterozygous mutations or hemizygous DNA deletions at these loci. This situation underlies a variety of human disorders that are inherited in a non-Mendelian fashion; that is, with phenotypic effects seen only after transmission of the mutant allele from one type of parent (90,91).

Thus, while most autosomal genes are expressed roughly equally from the two parental alleles, imprinted genes are expressed preferentially or completely from only one allele—paternal or maternal—depending on the specific imprinted gene under consideration. The complex molecular mechanisms involved ultimately produce differential epigenetic marks on the two parental chromosomes: typically allele-specific DNA methylation (ASM) and/or allele-specific histone modifications. As noted previously, these epigenetic marks are often different in male vs. female gametes, and for imprinted genes this allelic asymmetry is preserved, albeit with some post-zygotic changes, in one or more tissues of the offspring (92). In other words, imprinted genes are an important exception to the general rule that epigenetic marks become equalized on the two alleles during mammalian post-zygotic development. Interestingly, most imprinted genes have been found to reside in 100 kb to several Mb-sized gene clusters, which define sub-chromosomal imprinted domains. All of the best-studied imprinted domains have their own kilobase-scale *cis*-acting imprinting control region, often referred to as an imprinting center (IC) or a germline differentially methylated region (DMR). These ICs have acquired a crucial DNA methylation mark in the paternal or maternal germline, and they preserve this mono-allelic mark in one or more tissues of the offspring, leading by several different

**FIGURE 6-3** Ideograms of human imprinted genes. Ideograms were generated using <http://www.dna-rainbow.org/ideograms/>. Ideogram of each human chromosome known to have an imprinted gene based on the imprinted gene catalog last updated January 2011 (<http://igc.otago.ac.nz>) and recent literature. The G-bands—areas with proportional more A–T base pairs—are normally colored black in schematic representations. To compare the schematic ideograms with our rendered chromosomes, we colored the A–T bases black and the G–C bases white. Blue areas in the rendered chromosomes identify bases not known yet. Blue genes are paternally expressed and red genes are maternally expressed. Bold genes are implicated in growth and the underlined genes play roles in neurodevelopment. Genes in italics have no reported function in growth or neurodevelopment.

downstream mechanisms to mono-allelic expression in *cis* of several clustered imprinted genes.

Geneticists have long debated the *raison d'être* for this surprising non-Mendelian phenomenon. The paternal–maternal intergenomic conflict hypothesis was proposed early on by evolutionary biologists to explain the observed patterns of imprinting for growth-related imprinted genes, and it seems to be standing the test of time as the most likely biological rationale for imprinting (89). Key to this hypothesis is the well-substantiated observation that imprinted genes that are expressed from paternal alleles tend to drive increased growth of the fetus and placenta and/or promote neonatal activity including suckling, thereby placing a greater demand on maternal resources while, in contrast, imprinted genes expressed from maternal alleles tend to inhibit growth and down-regulate demands on the mother (93). Less well understood are the origins of imprinted gene expressions in the brain, and their effects on cognition and behavior. Emerging studies point to an as yet underinvestigated

role for a subset of brain-specific imprinted genes in normal neurodevelopment, cognition, and behavior, including certain major psychiatric disorders (94).

### 6.5.1 Androgenetic and Gynogenetic Tumors: Hydatidiform Moles and Ovarian Teratomas

Complete hydatidiform moles (CHMs) are trophoblast tumors arising from a defective oocyte that has been fertilized by one or rarely two sperms, followed by the retention of a diploid set of paternal chromosomes during early cell divisions and loss of the maternal chromosomes (95). This scenario typically leads to paternal uniparental disomy (UPD) for all chromosomes: thus almost all CHMs are androgenetic tumors, and the dys-regulated growth of these neoplasms is consistent with the frequent physiological roles of paternally expressed imprinted genes in promoting trophoblast proliferation (93). Women with CHM need to be followed after

evacuation of the mole, since these lesions can progress to malignant choriocarcinoma. Diagnosis is often straightforward but occasionally difficult; immunostaining of histological sections from suspected placental neoplasms for the proteins encoded by maternally expressed imprinted genes, including *CDKN1C* ( $p57^{KIP2}$ ) and *PHLDA2*, can be useful for diagnosis as CHMs will be negative for their expression while normal placenta and so-called partial moles will retain expression of these markers (96,97). In nearly all hydatidiform moles, the maternal chromosomes have been physically lost, but rare examples of biparental moles that retain the maternal genome have been described, which occur in families and/or repeatedly in successive pregnancies, suggesting a genetic predisposition. In these tumors, nonetheless there is markedly reduced expression of paternally imprinted/maternally expressed genes, indicating that the androgenetic gene expression state in these variant cases has resulted from failure of maternal imprinting, and that this state is biologically essential for tumor formation (98). Germline mutations in the *NLRP7* and *C6orf221* oocyte-expressed genes have now been identified in some women with this syndrome of familial biparental hydatidiform moles (99,100).

Mature cystic teratomas originate from a parthenogenetically activated oocyte after first meiosis, and are one of the most common types of benign ovarian tumors. The result is the formation of a cyst containing mature tissues from each of the three germ-cell layers. They usually contain disorganized, tridermal, mature components, in which ectodermal tissue predominates (101–103). Muter describes genetic imprinting as a major factor in the development of some of these tumors (103). We have recently identified a genome-wide disruption of normal methylation profiles at ICs in mature ovarian cystic teratomas validating early reports (104).

## 6.5.2 Genomic Imprinting and Human Disease

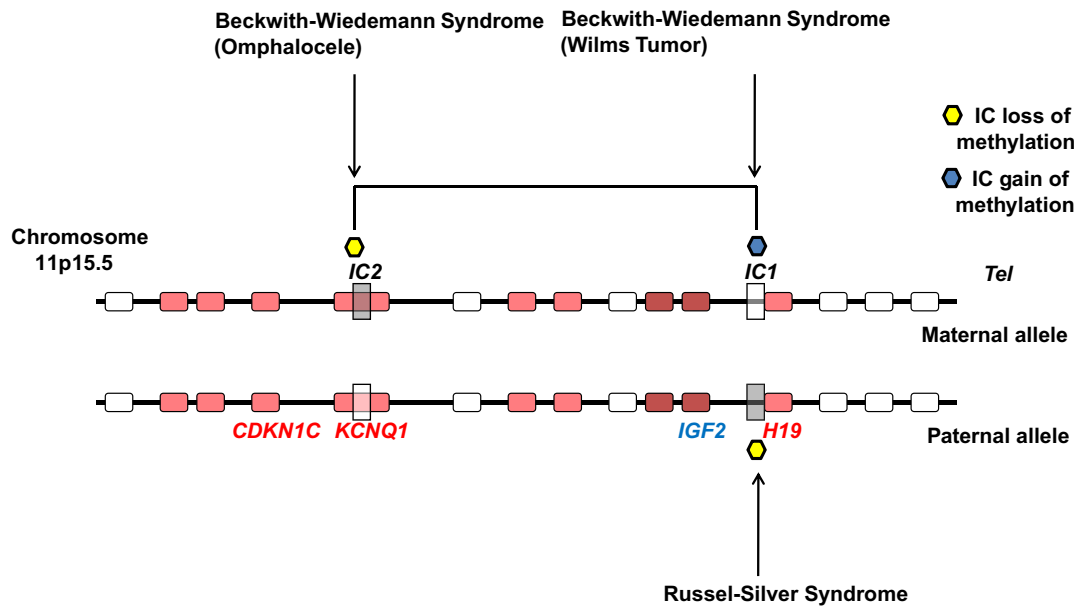

Imprinted genes typically function in growth regulation and neurodevelopment, and the corresponding disease phenotypes due to genetic or epigenetic aberrations in these genes indeed entail major abnormalities of intra-uterine growth or postnatal cognition and behavior (Figure 6-3). We will first discuss imprinting disorders that feature overgrowth or growth restriction as one of their major clinical characteristics.

**6.5.2.1 Beckwith–Wiedemann Syndrome.** This disorder is a rare, often sporadic, heterogeneous congenital overgrowth disorder with an incidence of ~1/13,700 live births (90,105,106). However, this is likely an underestimate as milder and overlapping phenotypes may not be ascertained. Clinically, diagnostic criteria include macrosomia (somatic overgrowth), macroglossia (large tongue), abdominal wall defects (omphalocele, often requiring surgical repair), ear creases and pits, kidney

malformations, neonatal hypoglycemia, visceromegaly, and somatic hemihyperplasia. Certain tissues and organs can also become disproportionately large (kidneys, liver). There is also an increased incidence of embryonal tumors (7.5%). Most common are Wilms tumor and hepatoblastoma, but a variety of other tumor types are seen, including neuroblastoma, rhabdomyosarcoma, and adrenocortical carcinoma.

Beckwith–Wiedemann Syndrome (BWS) is caused by epigenomic and/or genomic alterations in the imprinted gene clusters on chromosome band 11p15.5 (107). The 11p15.5 region can be subdivided into two distinct imprinted domains separated by a non-imprinted region (Figure 6-4), and lesions in each of these imprinted domains can cause BWS, albeit with some phenotypic differences between the two variants of this syndrome. Notably, Wilms tumors are more common in children with BWS due to epigenetic lesions in the *IGF2/H19*-imprinted domain (gain of CpG methylation in the *H19* DMR), while omphalocele is usually more severe in the larger group of cases of BWS that are caused by epigenetic lesions in the *KCNQ1/CDKN1C*-imprinted domain (108). *IGF2*, pathologically activated on the maternal allele in some cases of BWS, encodes a growth factor, while *CDKN1C*, repressed in many cases of BWS, encodes a cyclin-cdk inhibitor. Both of these genes are normally highly expressed in fetal development and have been shown to control growth in mouse models. Very importantly, most cases of BWS are due to purely epigenetic lesions (“epimutations”), either gain of CpG methylation on the maternal allele of the *H19* upstream DMR, which silences *H19* and activates the expression of *IGF2*, or the loss of methylation on the *KCNQ1* intronic DMR, which silences *CDKN1C* plus several nearby maternally expressed genes. These epimutations occur as epigenetic programming errors early in post-zygotic development, often resulting in tissue mosaicism for the cells carrying the epimutation. Cases of BWS with paternal UPD or trisomy encompassing band 11p15.5 are also well documented. Importantly, rare but informative BWS cases have also been described with structural DNA lesions (micro-deletions) in the *H19* DMR, or point mutations in the coding region of *CDKN1C*, providing genetic proof of the major causal roles of *CDKN1C* deficiency and *IGF2* biallelic expression, respectively, in the two main classes of this syndrome.

**6.5.2.2 Russell–Silver Syndrome.** This disorder is characteristically diagnosed in individuals with severe prenatal and postnatal growth compromise (109). Most cases of Russell–Silver Syndrome (RSS) are sporadic; occasionally there are familial cases. Prenatal growth restriction, with or without postnatal short stature, has been the most consistent feature described in patients categorized as RSS or RSS-like. Significant variation occurs in the remaining phenotypic features such as asymmetric growth of the extremities. Molecular results should therefore be examined in the context

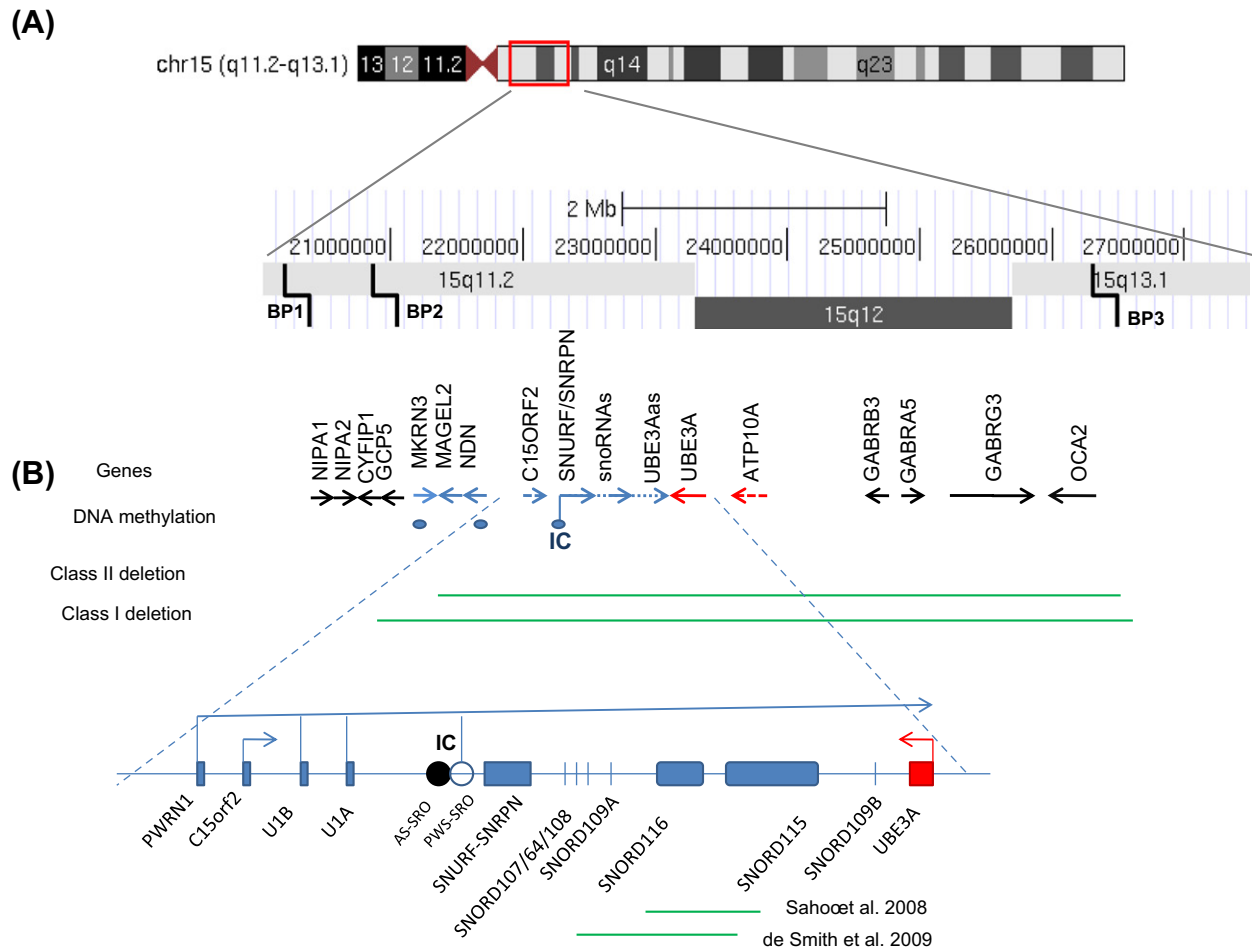

**FIGURE 6-4** Schematic representation of imprinted gene clusters on human chromosome 11p15.5. Imprinted genes are indicated as filled boxes and non-imprinted genes as empty boxes. Paternally expressed genes are indicated in blue and maternally expressed genes in red color. Hollow rectangles show the location on normally unmethylated IC and filled rectangles indicate that the IC is normally methylated. Methylation alterations—such as loss of methylation (yellow hexagon) and gain of methylation (blue hexagon)—show the locations of these changes in each of the two syndromes: BWS and RSS spectrum. In the telomeric domain are two imprinted genes: *H19* and insulin-like growth factor 2 (*IGF2*). *IGF2* is a paternally expressed fetal growth factor and *H19* is a noncoding RNA. IC1 is usually methylated on the paternal chromosome and unmethylated on the maternal chromosome. Normally, the *H19* gene is expressed from the maternal allele and *IGF2* from the paternal allele. Loss of methylation (LOM) at IC1 leads to biallelic expression of *H19* and no expression of *IGF2*, resulting in RSS. Conversely, gain of methylation (GOM) at IC1 leads to biallelic expression of *IGF2* and no expression of *H19* resulting in BWS. The centromeric domain contains several imprinted genes, including *KCNQ1*, *KCNQ1OT1* (long noncoding RNA within the *KCNQ1* gene, not shown in this figure), and *CDKN1C*. IC2 at the promoter for *KCNQ1OT1* regulates the expression of *KCNQ1OT1*, which is a paternally expressed noncoding transcript that further regulates *in cis* the expression of the maternally expressed imprinted genes in the centromeric domain. LOM at IC2 leading to biallelic expression of *KCNQ1OT1* is found in 50% of BWS patients. This epigenetic alteration leads to reduced expression of the growth-regulating gene *CDKN1C*.

of the clinical criteria used for ascertainment of the subjects. Maternal UPD for chromosome 7, a chromosome with known imprinted loci, has been found in 7–10% of RSS cases ascertained using stringent diagnostic criteria. Imprint dysregulation on human chromosome 7 can also cause the RSS phenotype. Epigenetic abnormalities at the *IGF2/H19* locus on chromosome 11 have been found in 20–40% of RSS cases depending on the selection criteria. The main phenotypic feature consistently seen among patients with *H19* DMR hypomethylation is the severe prenatal growth restriction with the postnatal maintenance of short stature (more than 2 SD below the mean). Hence, this form of RSS is essentially opposite, both in phenotype and epigenotype, to cases of BWS with *H19* DMR hypermethylation and somatic overgrowth. Duplication of maternal chromosome band 11p15 has also been reported in individuals with reasonably stringent RSS diagnostic criteria; again representing an opposite situation to a subgroup of BWS cases with duplication of the paternal copy of this same chromosomal region. Thus, a well-defined subgroup of RSS cases seems to result from *IGF2* deficiency. Whether loss of the noncoding *H19* RNA or a microRNA (miR-675) encoded within this gene, which occurs coordinately with the *IGF2* gene activation in both UPD and epimutation cases, also plays

a physiological role in some aspects of RSS and BWS is still under investigation.

### 6.5.2.3 Prader-Willi and Angelman Syndromes.

These two disorders are discussed together because they both map to the imprinted gene cluster on chromosome band 15q11–q13 (Figure 6-5). These are two distinct neurogenetic disorders, both occurring at a frequency of 1 in 15,000–25,000 live births (110). Prader-Willi Syndrome (PWS) is characterized by hypotonia and feeding difficulties early in life, with failure to thrive in early infancy, followed by a shift to excessive eating that can lead to morbid obesity at 1–6 years of age. Individuals with PWS also exhibit developmental delay, mild to moderate ID, a distinctive behavioral phenotype including temper tantrums and obsessive-compulsive features, short stature, hypogonadism, characteristic facial features, scoliosis, and non-insulin-dependent diabetes mellitus. Consensus diagnostic criteria for PWS were first developed by Holm et al. (111), and further revised based on molecular diagnostics (112). In contrast, Angelman Syndrome (AS) is characterized by microcephaly, severe ID, severe speech impairment, gait ataxia, seizures, and a unique behavioral profile including frequent laughter, smiling and excitability. Consensus diagnostic criteria were developed by Williams et al. (113).

**FIGURE 6-5** Schematic maps of the imprinted domains on chromosome bands 15q11–q13. (A) Arrows represent the genes (note that sizes of genes are not to scale). Colors of the arrows represent pattern of expression, blue: paternal, red: maternal, black: biallelic, and dashed arrows show unconfirmed monoallelic patterns of expression. The names of the genes are shown above the respective arrows. IC is an IC located upstream of *SNURF-SNRPN*. Blue circles show regions of differential DNA methylation on the maternal chromosome. BP1, BP2 and BP3 are recurrent breakpoints. Green lines indicate regions of typical deletions (class I and II) associated with Angelman syndrome (maternal deletions) and Prader-Willi syndrome (paternal deletions), and maternal duplications associated with ASD. (B) Zoom into the *SNURF-SNRPN-UBE3A* region. Circles are IC critical elements, black circle is the AS smallest overlapping region (AS-SRO), white circle is PWS-SRO. Boxes are genes, colors of boxes represent pattern of expression, blue: paternal and red: maternal. Arrows denote the direction of expression. *SNURF-SNRPN* is a multi-exonic gene, expressed in multiple isoforms, with the first 3 coding exons encoding SNURF, a protein of unknown function, and *SNRPN* encoding SmN, a spliceosomal protein involved in mRNA splicing. PWRN1, u1A, and u1B are alternative transcription start sites of *SNURF-SNRPN*. SnoRNAs are encoded within introns of *SNURF-SNRPN*, with individual genes for SNORD 107, 64, 108, 109A and 109B, while SNORD 116 and 115 are multi-copy gene clusters. The function of the snoRNAs is not completely understood, they are possibly involved in modulating alternative splicing/regulation nucleolar size. Some of the splice variants of *SNURF-SNRPN* span *UBE3A* (*UBE3A-as*), which possibly regulates imprinted expression of *UBE3A*. Green lines are small atypical deletions associated with PWS.

That these two distinct disorders both map to the imprinted domain on chromosome band 15q11–q13 is explained by the fact that this large (~2.5 Mb) imprinted region contains several paternally expressed (i.e. expressed in an imprinted fashion only from the paternal allele) genes, including *MKRN3*, *MAGEL2*, *NDN*, *C15ORF2*, *SNURF-SNRPN*, and a cluster of C/D small nucleolar (sno-) RNAs, plus a maternally expressed imprinted gene—*UBE3A*—and the *ATP10C* gene that exhibits polymorphic maternal allele expression (110,114). The expression of genes within the 15q11–q13 imprinted domain is regulated by an IC, containing two critical control elements located at the 5' end of *SNURF-SNRPN* (Figure 6-5). The differentially

methyated IC and the promoter regions of *MKRN3* and *NDN* are methylated only on the maternal allele.

Accumulated molecular data have shown that AS results from functional loss, via mutation, paternal UPD, or maternal deletion, or in rare but informative cases IC microdeletions or epimutations, of the maternally expressed *UBE3A* gene. Conversely, PWS arises from the functional loss of paternally expressed genes, no single candidate gene was identified to date; however, atypical microdeletions suggest the important role of sno-RNA *SNORD116*. The most frequent cause of both syndromes (~70%) is a de novo ~5–7 Mb deletion, typically visible by standard cytogenetics. These interstitial deletions involve the entire imprinting domain and several

nonimprinted genes (class I and II deletions) (110,115). In PWS, deletions occur on the paternal chromosome, whereas in AS deletions occur on the maternal chromosome. In 25–30% of PWS cases, loss of the active paternal 15q11–q13 genes result from maternal UPD for this chromosomal region, and conversely 2–5% of AS results from paternal UPD (110). No mutations in single genes have been demonstrated to date in PWS, but in 10% of AS cases mutations of the maternal copy of *UBE3A* have been documented (116,117). This gene encodes an E3 ubiquitin ligase a protein that functions in protein degradation. About 80% of the mutations occur de novo, and about 20% are inherited from unaffected mothers (118). By a mechanism that is not yet fully understood, maternal expression of *UBE3A* is only observed in the brain but not in other tissues, accounting for the neurobehavioral AS phenotype of deficient expression (119,120).

An IC defect is reported in 1–3% of PWS and 2–4% AS patients. This type of defect results from an acquisition of maternal-type imprint (gain of DNA methylation) on the paternal chromosome in PWS and conversely the loss of the maternal imprint (loss of DNA methylation) on the maternal chromosome in AS. In some cases the IC defects are pure epimutations, while in a small but informative group the IC defects are secondary to DNA microdeletions within the bipartite IC. The location of microdeletions is distinct in AS vs. PWS cases; the smallest region of overlap (SRO) of the microdeletions in PWS is 4.3 kb in size and is located within the *SNURF-SNRPN* exon1/promoter (121), while the AS SRO is 880 bp and is located more centromeric, about 35 kb upstream of exon1 of *SNURF-SNRPN* (122). For both syndromes, a microdeletion can be de novo, or inherited from an unaffected carrier parent, through the male germline in PWS and through the female germline in AS (110). However, as noted above, the majority of IC defects in both disorders are due to primary epigenetic alterations (epimutations), which can result from failure of imprint erasure/acquisition or maintenance. Failure of imprint maintenance occurs post-fertilization and results in somatic mosaicism, such that not all cells are affected by the IC defect. In PWS, somatic mosaicism is very rare, whereas in AS it occurs in about 40% of cases with IC defects (110). The percentage of normally methylated cells can vary from less than 1–40% and patients having more cells with normal methylation tend to have milder clinical symptoms (123). Of interest, the proportion of AS patients with an IC defect is increased to 25% in children born to sub-fertile couples or undergoing fertility treatments (124).

The relative contributions of specific paternally expressed genes to PWS are still not clear. Atypical small deletions (125,126) and balanced translocations within the *SNURF-SNRPN* locus (127–132) point to the importance of sno-RNA *SNORD116*, as they usually involve either deletion or transcriptional dysregulation of this gene, whereas DNA methylation and expression of the

genes centromeric to *SNURF-SNRPN* remain intact (110). However, as there are some atypical features seen in patients with microdeletions, it is likely that other genes within the imprinted cluster contribute to the PWS phenotype, as well as having potentially important roles in other clinical phenotypes. For example, an unbalanced translocation associated with the deletion of the paternal copies of *MKRN3*, *MAGEL2*, and *NDN* result in obesity and ID, without other features of PWS (133). Lastly, in contrast to PWS where most cases can be explained by genetic and/or epigenetic alterations at the 15q11–q13 imprinted cluster, 10–15% of suspected AS cases have no identifiable molecular alteration (110).

### 6.5.3 Differential Diagnosis, Epigenotype–Phenotype Correlations, and Genetic Counseling in Imprinting Disorders

Several disorders clinically resembling AS and PWS and could be considered if the molecular testing for AS and PWS is negative (110). For AS, often the most clinically relevant disorder in the differential is Rett syndrome, and for PWS it is maternal UPD of chromosome 14 (110). As discussed previously for BWS, there are certain epigenotype–phenotype correlations for PWS and AS. Haploinsufficiency for non-imprinted genes located within the deleted regions can contribute to more severe phenotypes compared to other genetic/epigenetic lesions cases for both AS and PWS (110). For example, hypopigmentation is a frequent finding in PWS patients with deletions due to loss of one copy of the *OCA2* gene (134). Haploinsufficiency of the *GABRB3* gene is suggested to play a role in susceptibility to severe seizures in AS deletion patients (135). The frequency of autism and psychosis is increased in UPD cases of PWS, but the molecular basis is unknown (136,137). Notably, the AS- and PWS-associated 15q11–q13 imprinted cluster plays an important role in autism spectrum disorder (ASD) susceptibility. Maternal duplications of 15q11–q13 with the same breakpoints observed in AS and PWS are currently the most frequent known genetic causes of autism, found in 1–2% of ASD case (138).

Identifying specific molecular defects in imprinting disorders provides important information for patient management and for estimating recurrence risk. Molecular diagnosis, which often consists of testing for abnormal DNA methylation in the relevant imprinted domains, can be done in an increasing number of imprinting disorders and is already widely applied in PWS/AS (domain in chromosome band 15q11–q13) and BWS/SRS (domains in chromosome band 11p15.5). The majority of molecular alterations within imprinting domains (UPDs, IC epimutations, and microdeletions) can be diagnosed in a simple fashion by assaying DNA methylation in the respective IC. Techniques such as Southern blot or PCR-based assays for DNA methylation (139,140) are useful in addition to the more recently

developed method— multiplex ligation-dependent probe amplification (141). The advantage of using MPLA is that it detects both methylation levels and copy number across several sites within the imprinted cluster. Thus, it can identify microdeletions within the IC in PWS and AS, which are important as they could be inherited from unaffected parents and are associated with 50% recurrence risk. MPLA cannot distinguish UPD from primary IC defects; however, in BWS, simultaneous gain of DNA methylation at H19 DMR and the loss of DNA methylation at *KCNQ1* intronic DMR strongly suggest the presence of chromosome 11p15 UPD. Additional testing for chromosome 11p15 UPD using either a PCR-based dosage assay or microsatellite genotyping should be undertaken if this molecular change is suspected, especially given the high frequency of somatic mosaicism. A normal DNA methylation pattern at chromosome 15q11–q13 makes the diagnosis of PWS highly unlikely as ~99% of PWS cases have de novo deletions, UPD, or IC defects. For AS and BWS, if no loss of DNA methylation at respective ICs is detected, sequencing of *UBE3A* or *CDKN1C*, respectively, should be performed. For SRS, DNA methylation is usually performed for the distal (H19) IC on chromosome 11p15.5 and the imprinted genomic regions at 7p13 and 7q32 (142).

If no molecular defects are identified by methylation and mutation screening, comparative genome hybridization arrays to identify small atypical deletions or duplications could be pursued. It should be kept in mind that identification of small deletions or duplications is dependent on the resolution of microarrays, which can vary significantly among different diagnostic laboratories. Although chromosome translocations, inversions, and duplication infrequently cause imprinting disorders, their presence is associated with a real risk of recurrence. A chromosome abnormality associated with an imprinting disorder may or may not have an associated methylation defect. Therefore, whether or not a methylation defect is present, high-resolution banding of the critical chromosomal region(s) should be considered for all individuals who have imprinting disorders.

Individuals with imprinting disorders and UPD have not to date been reported to transmit the molecular alteration or imprinting disorder to the next generation. In fact, theoretically this is very unlikely. Recurrence risk is usually low (<1%) in individuals with IC epimutations and imprinting disorders. This low risk implies that, in most cases, the IC defect can be rectified by normal germline reprogramming mechanisms. However, there are a small percentage of cases with IC defects that are heritable. These can be recognized from a positive family history or an associated genomic alteration. When inherited genetic alterations are present such as IC microdeletions in AS and PWS, *UBE3A* mutation in AS and *CDKN1C* mutation in BWS, the associated recurrence risk rises to 50%. Such genetic alterations segregate in a Mendelian fashion, but the penetrance of the imprinting disorder depends on which parent transmits the mutation. For example, a parent carrying a mutation in *CDKN1C* (BWS) or *UBE3A* (AS) has a 50% chance of transmitting the mutation, but the imprinting disorder is expressed only if the mother transmits the mutation, since the paternally transmitted gene, whether it carries a mutation or not, is normally silenced in the male germline.

## 6.6 GENETIC DISORDERS DUE TO GENES AFFECTING CHROMATIN STRUCTURE

A number of disorders have been described with mutations or deletions in genes that are important for maintaining normal epigenetic regulation. Loss of function of these genes can disrupt normal establishment, maintenance, or reading of epigenetic marks, thereby resulting in altered chromatin structure and gene expression. In most conditions of this type, we still do not understand precisely how the mutation is related to the phenotype of the human disease. Many of these disorders are associated with ID; other features include facial dysmorphism and various congenital anomalies (143–145). Examples of disorders caused by loss of function of such genes are shown in Table 6-1 and are described in the following.

**TABLE 6-1 X: Genes Causing Chromatin Disorders**

Gene	Function	Locus	Disorder	OMIM	References
<i>ATRX</i>	ATPase/Helicase	Xq21.1	Thalassemia/mental retardation syndrome, X-linked	#301040	Gibbons et al. (315)
<i>CHD7</i>	ATPase/Helicase	8q12.2	CHARGE syndrome	#214800	Vissers et al. (153)
<i>KDM5C</i>	H3K4 demethylase	Xp11.22	X-linked ID	#300534	Rujirabanjerd et al. (162)
<i>EHMT1</i>	H3K9 methyltransferase	9q34.3	Kleefstra syndrome	#610253	Kleefstra et al. (170)
<i>NSD1</i>	H3K36 methyltransferase	5q35.3	Sotos syndrome Weaver syndrome	#117550, #277590	Baujat and Cormier-Daire (175) Douglas et al. (176)
<i>MLL2</i>	H3K4 methyltransferase	12q13.12	Kabuki syndrome	#147920	Ng et al. (181)
<i>CREBBP</i>	Histone acetyltransferase	16p13.3	Rubinstein–Taybi syndrome	#180849	Petrij et al. (316)
<i>EP300</i>	Histone acetyltransferase	22q13.2	Rubinstein–Taybi syndrome	#180849	Roelfsema et al. (317)
<i>DNMT3B</i>	DNA methyltransferase	20q11.21	ICF syndrome	#242860	Xu et al. (203)
<i>MECP2</i>	Methyl binding protein	Xq28	Rett syndrome	#312750	Amir et al. (204)

## 6.6.1 Diseases Due to Aberrant Chromatin

**6.6.1.1 ATR-X Syndrome (*ATRX*).** Mutations in an X-linked gene—*ATRX*—cause  $\alpha$ -thalassemia/mental retardation syndrome, X-linked (ATR-X). This syndrome is characterized by severe ID, facial dysmorphism, urogenital anomalies, and  $\alpha$ -thalassemia. As the *ATRX* gene normally undergoes X inactivation, affected individuals are almost exclusively males, while females usually are unaffected due to preferential X inactivation of the chromosome with the *ATRX* mutation (146). The *ATRX* protein is involved in epigenetic regulation through two functional domains: an ATP/helicase domain and an ADD domain that shares homology with de novo methyltransferases. The ATP/helicase domain is proposed to be involved in nucleosome repositioning and making DNA more accessible for protein binding (147) while the ADD domain has been shown to bind histone H3 tails with the silencing mark H3K9me3, but not the active mark H3K4me3/2 (148). In terms of genomic targets, *ATRX* has been shown to localize to the nucleus in heterochromatin, telomeric/subtelomeric chromosomal regions, rDNA, and promyelocytic leukemia bodies (149–151). Furthermore, peripheral blood cells of ATR-X patients exhibit changes in DNA methylation of rDNA, sub-telomeric repeats, and Y chromosome-specific satellites (149). By ChIP-sequencing, it was established that in erythroid cells *ATRX* binds to CpG-rich tandem repeat sequences clustered at sub-telomeric regions, thereby affecting the expression of associated genes including  $\alpha$ -globin, which accounts for the  $\alpha$ -thalassemia phenotype of ATR-X syndrome (152).

**6.6.1.2 CHARGE Association (*CHD7*).** Nonsense or missense mutations and deletions resulting in haploinsufficiency of the chromodomain helicase DNA-binding protein *CHD7* cause the majority of cases of CHARGE association (*CHD7*) (153,154). Clinical diagnosis of *CHD7* is based on nonrandom associations of the following congenital abnormalities: Coloboma of the eye, Hear defects, Atresia of the nasal choanae, Retarded growth and development, Genital abnormalities, and Ear abnormalities/deafness/vestibular disorder (153,155). Studies in model organisms—*Drosophila* and mouse—have found phenotypes that overlap those found in humans (156,157). In *Drosophila*, reduced expression of *kismet/CHD7* results in deficits in axonal pruning, guidance and extension, as well as defects in memory and motor function. *Kismet* has also been shown to regulate the repressive histone H3 methylation mark of lysine 27 (158) and the loss of *kismet/CHD7* expression results in increased repressive chromatin marks, thereby repressing the expression of other genes than it would normally regulate. Similarly, in human cell lines, *CHD7* has been shown to bind to chromatin regions that are active as demonstrated by histone H3 lysine 4 (H3K4) methylation and DNase1 hypersensitivity of these binding sites (158).

### 6.6.1.3 X-linked Mental Retardation (*KDM5C*).

Mutations in the X-linked gene *KDM5C*, encoding a histone demethylase, cause a spectrum of phenotypes, ranging from syndromic to non-syndromic ID. The clinical features in males with *KDM5C* mutations include mild to severe ID, epilepsy, short stature, hyperreflexia, aggressive behaviors, and microcephaly (159–164). *KDM5C* escapes X inactivation, and has a functional Y-linked homolog—*KDM5D*—so female heterozygous mutation carriers are usually unaffected but sometimes demonstrate mild ID or learning difficulties (72). *KDM5C* have several conserved functional domains, including the Bright/ARID domain responsible for DNA binding; the catalytic JmjC domain; and two PHD domains responsible for histone binding (165,166). *KDM5C* can bind to the repressive histone mark H3K9me3 and can remove the active epigenetic mark H3K4me3/2, thus establishing a repressive chromatin state (167,168). *KDM5C* point mutations found in patients can suppress demethylase activity and/or H3K9me3 binding in vitro, depending on the location of the mutation (168). Chromatin immunoprecipitation (ChIP) in cell lines showed that *JARID1C* co-localizes with REST, a transcriptional repressor in the neuron-restrictive silencing elements, in the promoters of a subset of REST target genes, including *BDNF* and *SCN2A*, suggesting that the loss of *JARID1C* activity impairs REST-mediated neuronal gene regulation (169).

**6.6.1.4 Kleefstra Syndrome (*EHMT1*).** Haploinsufficiency of the *EHMT1* gene due to heterozygous deletions or mutations causes the 9q subtelomeric deletion syndrome, also known as Kleefstra syndrome (*EHMT1*). These individuals demonstrate moderate to severe ID, childhood hypotonia, and facial dysmorphism (170). *EHMT1* encodes a histone methyltransferase catalyzing mono- and dimethylation of H3K9 through its catalytic SET and PreSET domains (171,172). H3K9me2 is a euchromatic silencing mark (173). It has been shown in mice that *Ehmt1* forms a heteromeric complex with another H3K9 methyltransferase, *G9a*, and knockouts of either of these genes lead to very similar phenotypes in mice, including embryonic lethality and loss of H3K9 methylation (171,172). In conditional knockouts in the forebrain of *Ehmt1*, *G9a*, or both, behavioral abnormalities, including defects in learning, motivation, and environmental adaptation were observed (174). Furthermore, *Ehmt1/G9a* deficiency in the forebrain led to derepression of non-neuronal genes, suggesting that the role of the *Ehmt1/G9a* complex is to protect neurons from transcriptional noise. Distortion of this transcriptional homeostasis has been proposed to lead to the ID phenotype (174).

**6.6.1.5 Sotos Syndrome (*NSD1*).** Haploinsufficiency due to mutations or deletions of the *NSD1* gene, encoding a histone methyltransferase, causes Sotos syndrome (*NSD1*), an overgrowth condition associated with macrocephaly, facial dysmorphism, advanced bone age, and learning difficulties or mild ID (175). Some

mutations of this gene are associated with another overgrowth condition, Weaver syndrome (176). *NSD1* has a catalytic lysine methyltransferase SET domain and four zinc-binding PHD domains and functions primarily to mono- and dimethylate H3K36 (177). The role of H3K36 methylation is not completely understood; in model organisms it has been found within gene bodies of expressed genes and is associated with the suppression of intragenic transcriptional initiation (178). ChIP-CHIP experiments using promoter microarrays have shown that NSD1 binds to promoters of genes playing a role in various processes, such as cell growth/cancer, keratin biology, and bone morphogenesis (179). In addition, it was found that four of the NSD1 PHD domains bind histone H3 methylated at K4 and K9, and that the large majority of point mutations found in Sotos syndrome disrupt this binding (180).

**6.6.1.6 Kabuki Syndrome (*MLL2*).** Recently, the whole exome sequencing has uncovered heterozygous mutations in the *MLL2* gene as the cause of Kabuki syndrome, characterized by mild to moderate ID, multiple congenital anomalies, short stature, and typical facial features (181). *MLL2* belongs to the SET1 family of histone H3K4 methyltransferases. It has a catalytic SET domain, five PHD domains, and an HMG-I binding motif (182). *MLL2* is a part of a multi-protein complex that catalyzes mono-, di-, and trimethylation of H3K4 (183). H3K4 trimethylation is associated with active transcription (178) and the reduction of *MLL2* in human HeLa cells results in downregulation of a number of genes involved in cell adhesion, cytoskeleton organization, transcriptional regulation, and development (183). Interestingly in mice, *Mll2* has been shown to be crucial for the epigenetic re-programming that takes place before fertilization in oocytes by trimethylation H3K4, with deficiency of *Mll2* resulting in anovulation (184).

**6.6.1.7 Rubinstein–Taybi Syndrome (*CREBBP/EP300*).** Haploinsufficiency of chromosome 16p13.3 due to microdeletion or mutation in either the *CREB-binding protein* (*CREBBP*) or *E1A-binding protein* (*p300*) results in Rubinstein–Taybi syndrome (RSTS), characterized by multiple congenital anomalies, including postnatal growth deficiency, microcephaly, specific facial characteristics, broad thumbs, and big toes, and ID (185). Both of these homologous proteins contain a HAT domain and have been demonstrated to have overlapping functions, but there are some differences in expression patterns and necessity for specific processes and signaling molecule responsiveness (186–190). Using mouse models, the HAT activity has been demonstrated to be important for long-term potentiation, learning, and memory (191,192), which are in part regulated by histone acetylation-dependent transcription (193,194).

**6.6.1.8 ICF Syndrome (*DNMT3B* and *ZBTB24*).** Immunodeficiency, centromere instability, and facial anomalies (ICF) syndrome is a very rare disorder caused by mutations in *DNMT3B* in the majority of cases, and of

the epigenetic regulator gene *ZBTB24* in a minority of cases (195,196). Patients with ICF have low levels of immunoglobulins and reduced B- and T-lymphocyte counts (197). Most patients have DNA hypomethylation and chromatin under-condensation localized to juxtacentromeric (adjacent to the centromere) regions of chromosomes 1, 9, and 16, probably accounting for the diagnostic secondary chromosomal fusions observed in metaphase analyzes from affected lymphocytes (198–201). Aberrant hypomethylation also occurs in alpha satellite DNA, constitutive heterochromatin, Alu sequences, and some imprinted genes (200–203).

## 6.6.2 Disease Due to Abnormal Reading of Epigenetic Marks

**6.6.2.1 Rett Syndrome (*MECP2*).** Heterozygous mutations of the X-linked gene *MECP2* cause Rett syndrome in girls. Rett syndrome is characterized by developmental arrest between 5 and 18 months of age, followed by regression of acquired skills, loss of speech, stereotypical movements, microcephaly, seizures, and severe ID (204). The function of *MECP2* has been very extensively studied, but the mechanism by which its deficiency results in the phenotypes of Rett syndrome remains incompletely understood. Initially, *MECP2* was identified as a protein capable of binding methylated DNA (205). It was found to have abundant binding sites distributed throughout the genome and was demonstrated to function in the repression of transcription (206–208). The best-established mechanism by which *MECP2* downregulates gene expression is through recruitment of HDACs, which transform chromatin into a repressive state by removing acetyl groups from histones H3 and H4 (206,208,209). However, there is growing evidence that the role of *MECP2* in transcription regulation is more complex; for example, in mice it was shown to bind to the transcriptional activator CREB to activate transcription of a large number of genes in the hypothalamus (210). *MECP2* deficiency can lead to Rett syndrome through dysregulation of specific genes—such as *BDNF*—which has been shown to have an *MECP2*-binding site. Furthermore, reduction of *Bdnf* in mice mimics some features of the *Mecp2*-null mice phenotype (211) and *Bdnf* overexpression in *Mecp2* knockout mice can partially rescue the phenotype by improving their locomotor function, extending lifespan (212), and rescuing synaptic dysfunction (213). These data suggest that *BDNF* is indeed an important and clinically relevant *Mecp2* transcriptional target. Recent findings suggest that *MECP2* is almost as abundant as histone H1 in mouse neurons but not in glia (214), so *MECP2* function in neurons might affect genome-wide chromatin remodeling rather than only the regulation of the expression of specific genes. In addition, targeted deletion of *Mecp2* in mice results in increased expression of repetitive elements in neurons (214), prompting investigators to suggest

that this affects overall transcriptional noise in neurons, and the ability of neurons to respond adequately to environmental signals (215).

Lastly, it is relevant to consider that known functional interactions between the proteins involved in chromatin disorders suggest that their targets can in part overlap leading to shared or overlapping phenotypes such as ID. For example MECP2 and ATRX are components of the same chromatin remodeling complex (216,217). EHMT2, a partner of EHMT1, has been shown to be a component of the same protein complex as KDM5C (169). Identification of dysregulated genes and epigenetic marks in these chromatin disorders is the subject of ongoing research.

## 6.7 METHODS FOR STUDYING EPIGENETIC MARKS

### 6.7.1 Mapping DNA Methylation

Many techniques have been developed to study DNA methylation. One of the first methods to score DNA methylation at a specific locus was Southern blotting of genomic DNA digested with methylation-sensitive restriction enzymes (218). Certain restriction enzymes (e.g. *HpaII*, *SmaI*, *NotI*) that contain CpG as part of their recognition sequences do not cut that site when the C is methylated. Therefore, failure to cleave by a methyl-sensitive restriction enzyme is an evidence of DNA methylation at that site. Restriction enzymes can also be used in combination with microarray platforms to evaluate genome-wide DNA methylation patterns, including promoter methylation and allele-specific methylation (219,220).

The gold standard that allows for the comprehensive analysis of CpG sites is sodium bisulfite chemical conversion of DNA. Sodium bisulfite deaminates non-methylated dCs to dU residues; during subsequent PCR amplification, the latter are converted to A/T base pairs. However, if the C is methylated, the DNA sequence does not change (221). A number of methods have been developed to determine the levels of DNA methylation across multiple CpG sites. PCR primers can be designed to amplify specific genomic regions. Methylation-specific PCR provides a semi-quantitative measurement of DNA methylation levels. An alternative approach involves amplification of bisulfite PCR products followed by cloning and sequencing. This more-thorough approach permits DNA methylation levels of a larger number of individual CpG sites to be quantified, and the precise patterns of methylation to be displayed. One of the newer technologies—pyrosequencing—determines an absolute value for DNA methylation at individual CpG sites across a region. By combining sodium bisulfite conversion and microarrays or massively parallel Nextgen sequencing, genome-wide DNA methylation patterns can be determined for a large number of CpG sites (104,222).

### 6.7.2 Mapping Histone Modifications and Chromatin Structure

To determine the interaction of histone proteins with DNA, specifically histones that carry various modifications, chromatin immunoprecipitation (ChIP) is employed. This methodology detects the covalent modifications of histones bound to either active or inactive genes. Generally, cells or tissues are briefly fixed with formaldehyde to crosslink the proteins to the DNA. The fixed chromatin is fragmented, usually by sonication, to enable targeted analysis. The chromatin is next subjected to immunoprecipitation (IP) with an antibody specific for a given protein or, more often, a unique covalent modification of a certain residue (e.g. acetylation or methylation of lysine 9 of histone H3). After IP and the removal of the crosslinks, one can then amplify specific regions of interest by quantitative or semi-quantitative PCR. A PCR product indicates that the protein with that particular modification was associated with the DNA of the targeted genome region. Alternatively, ChIP can be combined with microarray technology or Nextgen sequencing to define genome-wide histone modification locations in various tissues and disease states. A large-scale project—the NIH Roadmap Epigenetics Mapping Consortium—has begun to map DNA methylation and a large number of histone modifications in a number of tissues, including normal, cancerous, and pluripotent cells, and the data from this project are being made publically available (223). Also important in the study of chromatin is the three-dimensional long-range interaction of regions of DNA and their associated proteins. To determine the three-dimensional interaction of chromatin segments at long distances from each other, a method called chromatin conformation capture (3C) has been developed (224). Newer modifications of the 3C method have been derived to facilitate genome-wide interaction mapping using next-generation sequencing (225).

## 6.8 CANCER EPIGENETICS

As amply demonstrated by the disorders discussed above, epigenetic aberrations can result in a diverse array of non-neoplastic human diseases. The contribution of epigenetic alterations to a number of different cancers has been studied even longer and equally intensively and is too broad to cover comprehensively; instead we restrict our discussion here to general principles, with selected illustrations. Changes in DNA methylation were the first epigenetic alteration identified in cancer (226), and subsequent work over three decades has shown that both hyper- and hypomethylation are important and pervasive pathogenic mechanisms both in early and late stages of human neoplasia (227). Not surprisingly, histone modifications and miRNA expression are also altered in cancer (228). It has become increasingly apparent recently that proteins regulating epigenetic marks, including histone

methyltransferases and demethylases, DNA methyltransferases, and chromatin remodeling SWI–SNF complexes, are also dysregulated, not just by over- or under-expression but also by recurrent cancer-associated somatic mutations. DNA methylation and histone methylation profiles, as well as miRNA signatures, are being used as epigenetic biomarkers to diagnose and predict recurrence risk for a number of tumor types, and it is hoped that such profiles will also become useful for individualizing anticancer therapies (229).

### 6.8.1 DNA Hypermethylation in Cancer

CpG hypermethylation in gene promoters is the best characterized epigenetic abnormality in human malignancies. A common paradigm in cancer epigenetics is hypermethylation of the CpG-rich promoter regions of tumor-suppressor genes, resulting in epigenetic silencing of these genes (14). Indeed, for some of the most important tumor suppressors—such as the *CDKN2A* gene encoding the p16 cell cycle inhibitor—promoter hypermethylation can be the most common mechanism underlying their functional loss during tumor formation, with the corresponding genetic pathways for loss of function (deletion/mutation) being utilized less commonly (230). Hypermethylated promoter DNA is associated with virtually every type of human tumor, with each type of tumor having its own signature of methylated genes, such as the methylation of *GSTP1* in prostate cancer, the von Hippel–Landau syndrome gene *VHL* in renal cancer, the mismatch repair gene *MLH1* in colon and endometrial cancers, and sometimes *BRCA1* in breast cancer (231–236). In some of these examples, the same tumor-suppressor gene is mutated or methylated as alternative pathways in the same tumor type: loss-of-function mutations in *MLH1* and *VHL* are found in the germlines of patients with hereditary colon and renal cancer, respectively, and these same genes are hypermethylated and silenced in sporadic tumors of the same histologic type (231,237).

While gain of DNA methylation is often discussed as a late event in tumor progression, CpG hypermethylation in specific sequences often occurs early in cancer formation, sometimes preceding tumorigenesis. Examples of early epigenetic aberrations can also be cited in other adult malignancies: in cigarette smokers, *CDKN2A* promoter methylation occurs in dysplastic bronchial epithelial cells prior to the formation of overt lung cancers (238), promoter hypermethylation of tumor suppressor genes is already detectable in the pre-malignant lesion Barrett esophagus (239,240). One of the best substantiated examples of a very early epigenetic lesion predisposing to subsequent tumor formation is the gain of methylation of the *H19* DMR on the maternal allele, which leads to the loss of imprinting of *IGF2* expression and can often be detected in non-neoplastic kidney cells both in BWS-associated and sporadic cases of the pediatric kidney cancer Wilms tumor (227).

DNA hypermethylation has attracted much attention as a biomarker for cancer detection and classification. To be clinically applicable, an ideal tumor biomarker must be specific for cancer, and readily detectable in clinical specimens obtained through minimally invasive procedures. DNA hypermethylation seems to fulfill these requirements and has been considered to be a promising biomarker. Examining the methylation of a subset of genes (*GSTP1*, *APC*, *RASSF1*, and *MDR1*) distinguished primary prostate cancer from benign prostate tissues with sensitivities and specificities of greater than 90% (241,242). DNA methylation alterations can be detected and used as biomarkers in feces for colorectal cancer, urine for bladder cancer screening, and sputum to predict the occurrence of lung cancer (243–245). However, for reasons that are complex but partly financial, these types of tests largely remain at the research stage and have not yet been widely adopted in clinical practice.

### 6.8.2 DNA Hypomethylation in Cancer

Global DNA hypomethylation in cancer cells was in fact identified prior to promoter hypermethylation (246), with studies indicating that genome-wide 5-methyl-C is reduced on an average of 10% in a number of different tumor types (226,247). Thus, the net decrease in the genomic methyl-C content in cancer cells often exceeds the localized increases in DNA methylation (248). There is some evidence that hypomethylation of DNA can result in genomic instability leading to mutations, deletions, amplifications, inversions, and translocations (249). Poor prognosis in colon cancer is associated with hypomethylation of repetitive elements (250). Hypomethylation can also lead to the reactivation of silenced genes and miRNAs leading to a cascade of aberrant expression (251,252). While most abnormalities in DNA methylation in human cancers cannot yet be explained by a clear genetic mechanism, there are at least several recurrent cancer-associated somatic mutations, in the *IDH1/2*, *TET2*, and *DNMT3A* genes, that have been proposed as candidates for explaining altered DNA methylation in certain tumor types such as AMLs and MDS (253).

### 6.8.3 Abnormalities of Histone Modifications in Cancer

Epigenetic alterations in cancer are not restricted to DNA methylation. Genome-wide mapping of histone marks has demonstrated global reductions in acetylated H4 lysine 16 (H4K16ac) and H4 lysine 20 trimethylation (H4K20me3), both resulting in or correlating with repression of gene expression (254). HDACs have been found to be overexpressed in a number of cancer types, and in some cancers that can be the dysregulation of HATs due to translocations resulting in deleterious gene-fusion products (255–257). Aberrant histone methylation of H3K9 and H3K27 also results in gene silencing

in many cancers (258,259). EZH2, a histone methyltransferase of H3K27, is frequently overexpressed in breast and prostate tumors, in addition to other tumors (260–262). As is true for aberrant DNA methylation, most abnormalities in histone modifications in cancer are not yet explained by a single genetic lesion. However, with high-coverage sequencing technologies an increasing number of chromatin-modifying enzymes, such as CREB, JARID1C, EZH2 and SWI/SNF family proteins hSNF5/INI1 and PBRM1, are now being found mutated in specific types of human cancers (263–267).

#### 6.8.4 Aberrant miRNA Expression in Cancer

Comparisons of tumor tissues and corresponding normal tissues have revealed global changes in miRNA expression during tumorigenesis (268). In chronic lymphocytic leukemia, *miR-15* and *-16*, which target the anti-apoptotic gene *BCL2*, are downregulated (269). Similarly, *let-7* that targets the oncogene *RAS* is downregulated in lung cancer (269). Upregulation of *miR-21* that targets *PTEN* has been shown to occur in glioblastoma (270). These alterations in miRNA expression may occur through a number of mechanisms including chromosomal abnormalities, transcription-factor binding, and epigenetic alterations (271). Silencing of miRNA expression has been shown to occur by aberrant hypermethylation in a number of cancers (272,273). As is true for the other epigenetic factors discussed above, the role of miRNA dysregulation in cancer has been validated genetically by findings of DNA deletions encompassing miRNA genes, for example, on chromosome 13 in chronic lymphocytic leukemias (274).

#### 6.8.5 Therapies Targeting Epigenetic Modifications in Cancer

Two classes of medications—DNA methylation inhibitors and HDAC inhibitors—have been approved by the US Food and Drug Administration as treatment for cancer (275). The DNA methylation inhibitors—5-azacytidine (azacytidine) and 5-aza-2'-deoxycytidine (decitabine)—are nucleoside analogs that get incorporated into the genomes of growing tumor cells and act as suicide inhibitors of DNA methyltransferase enzymes, leading to progressive loss of DNA methylation with each S-phase of the cell cycle. These medications have been approved for use in the treatment of MDS and have shown some promise for treating AML and other hematological malignancies (276). The HDAC inhibitor vorinostat (suberoylanilide hydroxamic acid) is being used with good results in treating patients with cutaneous T-cell lymphoma in the United States (277). Beyond treatment for cancers, such medications are being used and developed to treat a wider spectrum of diseases. Resveratrol, a natural compound in red wine, which inhibits sirtuins (a family of HDACs) is being evaluated as treatment for

type II diabetes and metabolic syndrome (278). Valproic acid (VPA), also an HDAC inhibitor, is currently used to treat seizures and mood disorders (279,280), and VPA in combination with other medications has been shown to inhibit cancers in vitro (281). The wide array of epigenetic alterations identified in human disease could present valuable targets for approved medications as well as for novel ones that have yet to be developed.

### 6.9 ENVIRONMENTAL INFLUENCES ON EPIGENETIC TRAITS

Transgenerational effects of the environment on our epigenome were recently documented for two tragic historical events: the Dutch hunger winter (1944) and the great Chinese famine (1958–1961). Studies of children born following these periods are reported to have an increase risk for schizophrenia (282,283). Children who were conceived during the Dutch famine had six decade later changes in DNA methylation in the *IGF2* gene which encodes a growth hormone critical for normal embryonic development (284). These data constitute the first concrete evidence that in humans the mother's diet early in pregnancy can directly affect the programming of the epigenome early in utero that shape our development later in life.

The role of diet and environment in the expression of imprinted genes has not been extensively explored. We are only beginning to understand which environmental signals can alter methylation of specific genes or the genome as a whole. There is evidence that environmental exposure to compounds such as cadmium (285) and arsenic (286) may be a predisposing factor that leads to epigenetic instability, aging, and cancer.

Both folate and the enzyme methyltetrahydrofolate reductase (MTHFR) are important for DNA synthesis and methylation. In fact, mice lacking the enzyme MTHFR have been shown to have decreased global DNA methylation. In humans, MTHFR enzyme activity depends on an individual's genotype for the functional polymorphism MTHFR 1298A>C and correlates positively with the level of global DNA methylation (287). Further, humans on a folate-depleted diet demonstrate decreased global DNA methylation (288). Conversely, in a study of adult males on hemodialysis, adding an exogenous source of folate led to an increase in both global and locus-specific DNA methylation, including *H19*, *IGF2*, and *SYDL1* (289). Lastly, dietary supplementation with folic acid and B vitamins has been clearly shown to modify tumor incidence in mouse models (290,291).

### 6.10 ABNORMALITIES IN EPIGENETIC PROGRAMMING LINKED TO INFERTILITY AND ASSISTED REPRODUCTION

In mice and humans, oocytes retrieved following hormonal induction or embryos studied after in vitro culture have shown methylation and/or expression anomalies in

several imprinted genes (292–295). Studies of human oocytes harvested after medical hormonal induction showed loss of methylation at the maternal *MEST/PEG1* DMR on chromosome band 7q33 (296) and gain of methylation at the maternal *H19* DMR (IC1) on chromosome band 11p15.5 (295). Increasing attention has recently been focused on reports of increased rates of epigenetic errors in human following infertility/ART. In particular, two rare epigenetic disorders—BWS and AS—exhibited an increased incidence in retrospective studies (odds-ratios 6–17 and 6–12, respectively) in children born following infertility/ART (297–302). The data are especially compelling in that the increased incidence is attributable to an increase in specific epigenetic errors at two different chromosomal locations, with both locations being affected by abnormal imprinting on the maternal (oocyte-derived) alleles. Furthermore, in ART-conceived AS and BWS patients, loss of maternal methylation at their respective DMRs (chromosomes 15q11 and 11p15) occurs 8 and 1.9 times more often, respectively, than in individuals born from spontaneous conceptions (124,303,304). Such evidence supports the hypothesis that ART-conceived children have an increased rate of epigenetic errors over those in the general population.

In humans, it is still unclear whether maternal loss of methylation observed in children post ART is the result of the procedure itself or of an underlying infertility with oocyte abnormalities in the couple seeking ART interventions, or both. However, idiopathic male infertility is also associated with aberrant methylation at both maternal and paternal alleles, suggesting that male germ cells represent another potential source for methylation defects in children conceived via ART (305,306). Recently, ovarian stimulation (part of subfertility/infertility treatment) was linked to perturbed genomic imprinting at both maternally and paternally expressed genes. These data demonstrate that superovulation has dual effects during oogenesis: disruption of imprint acquisition in growing oocytes, and the disruption of a maternal-effect gene product subsequently required for imprint maintenance during preimplantation development (307).

### 6.11 IN UTERO EPIGENETIC PROGRAMMING OF ADULT TRAITS AND DISEASE

The Developmental Origins of Health and Disease (DOHAD) hypothesis, pioneered by David Barker (308), has predicted among other things that maternal stress during pregnancy (dietary inadequacy, toxic exposures, and perhaps psychological stress) might lead to persistent epigenetic changes in the fetus, which could play a role in modulating the subsequent onset of adult cardiovascular, metabolic, and psychiatric diseases. In mice, maternal behavior in the neonatal period may correlate with epigenetic programming of adult behavior. Recent studies have indicated that mothers showing strong

nurturing behavior toward their pups, by frequently licking and grooming their offspring, produce alterations in the patterns of DNA methylation; for example, in the promoter of the glucocorticoid receptor gene, in the hippocampus of their pups (309). This area of research has now become quite active and it will be important to follow progress in this area over the next several years.

### 6.12 GENETIC–EPIGENETIC INTERACTIONS

With the exponentially increasing volume of human genetic data from SNP and DNA copy number analyses on microarrays, genome-wide association studies (GWAS), and “post-GWAS” studies such as whole exome and whole genome sequencing, it becomes crucial to consider interactions between the genome and the epigenome. In principle, these interactions can be of two types: interactions in *cis*, in which the local DNA sequence and haplotype can affect the pattern of epigenetic marks on a given allele, and interactions in *trans*, in which the overall genome, including mutations, DNA gains and losses, and whole chromosomal aneuploidies, can affect epigenetic patterns at various sites distributed across all the chromosomes. A small but increasing number of studies are starting to address these central questions about genome–epigenome interactions. By analyzing multiple tissue samples from multiple human individuals using high-throughput genetic and epigenetic profiling methods, these studies are starting to uncover recurrent and highly predictable genome–epigenome interactions.

In 2008, Kerkel et al. (220) used the MSNP method; the pre-digestion of genomic DNA by methylation-sensitive restriction enzyme(s) followed by probe synthesis and hybridization to SNP arrays, to examine ASM in several human tissues. Their study was designed to detect new examples of imprinted genes, but instead they found numerous examples of previously unsuspected ASM at loci outside of imprinted regions. Most of these examples of non-imprinted ASM showed a strong correlation of CpG methylation patterns with local SNP genotypes, indicating *cis*-regulation of this epigenetic phenomenon. That paper was quickly followed by other reports examining various types of human cells and tissues for ASM or similar phenomena of methylation quantitative trait loci (mQTLs) and allele-specific transcription factor binding (ASTF). All of these papers confirmed that for the majority of genes and intergenic regions showing strong ASM, mQTLs, or ASTF, the allelic asymmetry is dictated not by parent of origin but rather by local SNPs; that is, by the haplotype in which the epigenetic pattern is embedded (310). Thus, while ASM due to parental imprinting is a potent mechanism for regulating functional gene dosage, it affects fewer genes than this more newly recognized phenomenon of haplotype-dependent ASM. In parallel with this work, many laboratories have used

microarrays and Nextgen sequencing to map the related phenomena of haplotype-dependent allele-specific RNA expression (ASE) and eQTLs, which turn out to affect up to 10% of human genes.

Importantly for clinical genetics, these widespread phenomena of haplotype-dependent ASM, ASTF, and ASE, in contrast to imprinting, do not violate any Mendelian principles: while the allele-specific epigenetic patterns are not actually passed through the germline, in each generation these patterns are reestablished and maintained in the fetal and adult tissues under the strong *cis*-acting influence of the local DNA sequence. So for counseling purposes, each locus with haplotype-dependent epigenetic asymmetry can be thought of as inherited with the DNA sequence as a Mendelian trait.

Recent data have indicated that there can also be *trans*-acting effects of chromosomal aneuploidies on epigenetic patterns in human tissues. In particular, the chromosomal aneuploidy that causes Down syndrome (trisomy 21) has been shown to produce gene-specific and highly recurrent changes in DNA methylation in blood leukocytes including T-lymphocytes (311). Additional studies are in progress to test for this phenomenon in brain cells with trisomy 21, and in other situations such as cancer cells with recurrent simple chromosomal aneuploidies.

### 6.13 THE FUTURE: EPIGENOMICS

As we have highlighted throughout this chapter, the role of epigenetic marks in translating the primary genomic sequence has now moved to the forefront of human genetics, with clear implications for our understanding of human development and disease. A number of initiatives have now been implemented to define human epigenetic patterns at high resolution with complete genomic coverage. The technology is now available to investigate multiple tissue-specific epigenomes in humans, and the NIH Roadmap Epigenomics Mapping Consortium ([www.roadmapepigenomics.org](http://www.roadmapepigenomics.org)) was launched to produce a public resource of human epigenomic data to catalyze basic biology and disease-oriented research (223). Another parallel initiative is the NIH Epigenomics of Health and Disease Roadmap Program, which funds investigator-initiated research. While a good part of what we know so far about epigenetics in disease has come from cancer research, it is telling that most of the initial research grants from this program have been targeted to other complex diseases ranging from Alzheimer disease to adult heart disease and diabetes to autism. These initiatives interface with the International Human Epigenomics Consortium, which was established to accelerate and coordinate epigenomics research worldwide (312). These data should provide keys to unravel genetic and environmental factors that impinge on epigenomes to affect normal processes such as development and aging and lead to human diseases when these processes go awry.

### Biographies

**Rosanna Weksberg, MD, PhD**, is a Professor of Pediatrics and Medical Genetics at the Hospital for Sick Children and the University of Toronto. She has worked on human imprinting disorders and growth-related conditions since 1995. Her research has, more recently, included elucidation of the epigenetic basis and environmental contributors to neurodevelopmental disorders such as early onset psychosis and autism, as well as the identification of new imprinted genes. An important complementary research focus of the laboratory involves the characterization of the effects of both genetic variation and environmental exposures on epigenotype.

**Darci Butcher** obtained her BSc in Honors Genetics and her PhD in Biochemistry at the University of Western Ontario, London, ON. She is currently a postdoctoral fellow in Dr. Weksberg's laboratory in the program of Genetics and Genome Biology at the Hospital for Sick Children where her current research focuses on epigenomics of psychiatric disorders, intellectual disability, the effect of gestational diabetes on the fetus and late effects of medication on paediatric cancer survivors.

**Daria Grafodatskaya** graduated from Novosibirsk State University (Russia). She has obtained her doctoral degree at the Department of Animal Sciences at Swiss Federal Institute of Technology. Further, she has completed postdoctoral training at the University of Cambridge, UK. She is currently working as a research fellow in Dr. Weksberg's laboratory in the program of Genetics and Genome Biology at The Hospital for Sick Children, and her research is focused on the role of epigenetics in autism and intellectual disability.

**Sanaa Choufani** obtained her PhD from the Department of Cellular Biology at Université de Sherbrooke, Sherbrooke, QC. Dr. Choufani completed her postdoctoral training in genetics and in epigenetics respectively with Dr. Stephen Scherer and Dr. Rosanna Weksberg at The Hospital for Sick Children. Dr. Choufani is currently a Research Associate in the Genetics and Genome Biology program at The Hospital for Sick Children in Dr. Weksberg's laboratory. Her research focuses on the identification of new imprinted genes and their role in normal development. In addition, she studies the epigenetic basis of growth dysregulation in the cancer predisposition disorder, Beckwith-Wiedemann syndrome. She is also investigating the effects of assisted reproductive technologies on genomic imprinting and their impact on human health and development.

**Dr. Benjamin Tycko, MD, PhD**, is a Professor of Pathology and Cell Biology in the Institute for Cancer Genetics and Taub Institute on Alzheimer's disease and the Aging Brain at Columbia University. Dr. Tycko's lab has had a continuous research program on the role of epigenetics and DNA methylation in normal mammalian development and in diverse human disease processes and developmental disorders, including cancer, Down syndrome, Alzheimer's disease, and most recently autoimmune diseases. Key areas of current emphasis include (i) mechanistic studies on genetic-epigenetic interactions that occur in cis and in trans in human tissues and (ii) mouse models to elucidate the function of differentially methylated genes.

# CHAPTER 7

## Human Gene Mutation in Inherited Disease: Molecular Mechanisms and Clinical Consequences

*Stylianos E Antonarakis*

Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland

*David N Cooper*

Institute of Medical Genetics, Cardiff University, Cardiff, UK

### 7.1 INTRODUCTION

A wide variety of different types of pathogenic mutations have been found to cause human inherited disease, with many diverse mechanisms being responsible for their generation. These types of mutations include single base-pair substitutions in coding, regulatory, and splicing-relevant regions of human genes, as well as micro-deletions, micro-insertions, duplications, repeat expansions, combined micro-insertions/-deletions (“indels”), inversions, gross deletions and insertions, and complex rearrangements. A major goal of molecular genetic medicine is to be able to predict the nature of the clinical phenotype through ascertainment of the genotype. However, the extent to which this is feasible in medical genetics is very much disease-, gene-, and mutation-dependent. The study of mutations in human genes is nevertheless of paramount importance for understanding the pathophysiology of inherited disorders, for optimizing diagnostic testing as well as in guiding the design of new therapeutic approaches.

The first description of the precise molecular defect in a human disease (the sickle cell mutation, a Glu to Val substitution at the 6th codon of the  $\beta$ -globin (*HBB*) gene) was identified by Ingram in 1956 (1) who found that the difference between hemoglobin A and hemoglobin S lays in a single tryptic peptide. His analysis was made possible by the methods developed by Sanger for determining the structure of insulin and Edman to effect the stepwise degradation of peptides. This was followed, just over 30 years ago, by the characterization of the first heritable human gene mutations at the DNA level: gross deletions

of the human  $\alpha$ -globin (*HBA*) and  $\beta$ -globin (*HBB*) gene clusters giving rise to  $\alpha$ - and  $\beta$ -thalassaemia (2) and a single base-pair substitution (Lys17Term) in the human  $\beta$ -globin (*HBB*) gene causing  $\beta$ -thalassaemia (3). Since then, continuous technical advances have potentiated the identification of numerous disease-related genes and the discovery of thousands of underlying pathological lesions (4). Single base-pair substitutions (67%) and micro-deletions (15.6%) are the most frequently encountered mutations in the human genome, the remainder comprising an assortment of micro-insertions (6.5%), indels (1.5%), gross deletions (6.6%), gross insertions and duplications (1.4%), inversions, repeat expansions (0.3%), and complex rearrangements (1.0%).

The vast majority of mutations listed in Human Gene Mutation Database (HGMD) reside within the coding region (86%), the remainder being located in either intronic (11%) or regulatory (3%, promoter, untranslated, or flanking regions) sequences. Mutations may interfere with any stage in the pathway of expression from gene activation to synthesis and secretion of the mature protein product. The question of the proportion of possible mutations within human disease genes that are likely to be of pathological significance, is one that is difficult to address because it is dependent not only on the type and location of the mutation but also on the functionality of the nucleotides involved (itself dependent in part upon the amino acid residues that they encode), which is often hard to assess (5–10). In addition, some types of mutations are likely to be much more comprehensively ascertained than others, making observational

comparisons between mutation types an inherently hazardous undertaking.

Different types of human gene mutations may vary in size, from structural variants (SVs) to single base-pair substitutions, but what they all have in common is that their nature, size, and location are often determined either by specific characteristics of the local DNA sequence environment or by higher order features of the genomic architecture (11). This chapter attempts to provide an overview of the nature of mutations causing human genetic disease and then considers their consequences for the clinical phenotype. Two online databases, which interested readers may consult, contain information on known disease-related (pathogenic) mutations: the HGMD (<http://www.hgmd.org>) and *Mendelian Inheritance in Man* (<http://www.ncbi.nlm.nih.gov/Omim/> and <http://omim.org/>).

## 7.2 MOLECULAR MECHANISMS OF MUTATION CAUSING HUMAN INHERITED DISEASE

### 7.2.1 “Neutral Variation”/DNA Polymorphisms

The term *polymorphism* has been defined (12) as a “Mendelian trait that exists in the population in at least two phenotypes, neither of which occurs at a frequency of less than 1%” Polymorphisms are not therefore rare. Indeed, there is enormous variation in the DNA sequences of any two randomly chosen human haploid genomes. Clearly, not all variations within a gene result in the abnormal expression of protein products. Indeed, single nucleotide substitutions/polymorphisms (SNPs) occur in 1/~600–1200 nucleotides in intervening sequences and flanking DNA (13–18). These substitutions represent the most common form of DNA polymorphism that can be used as markers for specific regions of the human genome. Similarly, some single nucleotide substitutions in the coding regions of genes may also be normal (nonpathogenic) polymorphic variants even if they result in nonsynonymous substitutions of the polypeptide product (19). For example, there are three common forms of the  $\beta$ -globin (*HBB*) gene on chromosome 11p; these forms differ at five nucleotides, one of which lies within the first exon of the gene and results in a synonymous codon. The average human gene contains >120 biallelic polymorphisms, 46 of which occur with a frequency >5%, with five occurring within the coding region (20).

Some polymorphisms entail the alteration of an encoded amino acid, for example, the Lewis *Le* alleles of the *FUT3* gene (21), whereas others may introduce a stop codon that serves to inactivate the gene in question, for example the secretor *se* allele of the *FUT2* gene present in 20% of the population (22). However, not all polymorphisms are SNPs. Examples of other types of gene-associated polymorphisms in the human genome include triplet

repeat copy number (e.g. in the *FMR1* gene; see 9.2.1.3), gross gene deletion (e.g. *GSTM1* and *GSTT1*; (23)), gene duplication (e.g. *HBG2*; (24)), intragenic duplication (e.g. *IVL*; (25)), micro-insertion/deletion (e.g. *PAIL1*; (26)), indel (e.g. *APOE*; (27)), gross insertion (e.g. the inserted *Alu* sequence in intron 16 of the *ACE* gene; (28)), inversion (e.g., the 48 kb Xq28 inversion involving the *EMD* and *FLN1* genes; (29)), and gene fusion (e.g. between the *RCP* and *GCP* visual pigment genes; (30)). Functional polymorphisms may occur within the coding region (31) or regulatory regions (32) of a gene or may impact on pre-messenger RNA (mRNA) splicing (33) and can therefore have consequences for protein structure/function, gene expression, or mRNA splicing. It can be seen that the mutational spectrum of polymorphisms in the human genome is qualitatively different to that underlying human disease; they may vary in terms of location and frequency but otherwise they display remarkable similarities indicative of the same underlying mutational mechanisms.

It is likely that some SNPs, whether frequent or rare, alter the risk of common complex human phenotypes (“functional SNPs”). A public SNP database now contains more than 10 million entries (dbSNP; <http://www.ncbi.nlm.nih.gov/SNP/index.html>). An international project has recently been completed, termed the “HapMap project” (34–36), the goal of which was to define the patterns of common SNP genetic variation in a sample of 270 DNAs from individuals of European, African, Chinese, and Japanese origin (<http://www.hapmap.org/>). The data obtained from this project constitute ~2.8 million SNPs and are publicly available. The results of this project are likely to contribute significantly to our understanding of both common and rare human genetic disorders and traits. Furthermore, recent advances in high-throughput sequencing have led to the discovery of a large number of individually rare polymorphic variants in samples from the 1000 genomes (37) and other projects. The recent version of the dbSNP database (<http://www.ncbi.nlm.nih.gov/projects/SNP/>) contains more than 12.5 million variants. The protein-coding regions of a typical human genome (also known as the exome) contain 9000–11,000 nonsynonymous variants, ~100 nonsense codons, and 35 splice variants (38). Analysis of 54 human genomes, recently sequenced by Complete Genomics (<http://www.completegenomics.com>), revealed 3,700,000–4,700,000 single nucleotide variants per genome; the frequency of these variants was not identical in various fractions of the genome and is related to regional evolutionary constraints. Figure 7-1 illustrates that the protein-coding fraction of the genome, which is under evolutionary pressure, contains the smallest number of variants per kilobase (kb); by contrast, the repeat fraction of the genome and the intergenic regions, which presumably evolve neutrally, contain almost double the number of variants per kilobase.

### Nucleotide diversity in different genomic regions

- Genomic variants from CompleteGenomics, 54 unrelated individuals from different ethnic groups ([www.completegenomics.com](http://www.completegenomics.com))
- Genomic regions drawn from UCSC genome browser (<http://genome.ucsc.edu>)

**FIGURE 7-1** Nucleotide diversity (equivalent to frequency of polymorphic variants) in different genomic regions. The genomic variants analyzed are from the whole genome sequences of 54 unrelated human genomes (see text).

Another form of polymorphic variation in our genome is the presence of variable numbers of tandem repeats. The repeat unit can be 10–60 nucleotides in length and many different alleles may exist at a given locus (39,40). The combination of a VNTR and single nucleotide substitutions within the repeat unit results in an extremely high level of polymorphic variability, which can be used as a unique bar code to distinguish different individuals (41). The introduction of the polymerase chain reaction (PCR) (42) permitted the rapid detection and analysis of variation in short sequence repeats (SSRs), for example (GT)<sub>n</sub> repeats (43,44). These are common polymorphisms that occur on average once for every 50kb of genomic DNA. The SSRs also display many alleles and the repeat unit can be two, three, four, five, or more nucleotides. Poly(A) tracts may also be polymorphic, exhibiting variation in the number of A residues (45); many of these polymorphisms are localized at the ends of *Alu* repetitive elements. Another kind of polymorphism in the human genome involves the presence or absence of retrotransposons (i.e. *Alu* or LINE repetitive elements or pseudogenes) at specific locations (46,47). Duplicational polymorphisms in some human genes, for example *HBA1*, *PRB1-4*, *HBZ*, *CYP21/C4A/C4B* have been known for some time (47,48). More recently, however, the use of comparative genomic hybridization against BAC or oligonucleotide arrays has revealed extensive copy number polymorphism/variation (CNP

or CNV) of sizeable genomic regions (49–51). Details of many thousands of such genomic variants may be found in the following databases: *CNV Project*, <http://www.sanger.ac.uk/humgen/cnv>, and *Database of Genomic Variants*, <http://projects.tcag.ca/variation>. A first CNV map of the human genome of the 270 “HapMap” individuals revealed a total of 1440 CNV regions covering ~360 megabases (Mbs) (12% of the genome) (52). More recently, high-resolution tiling oligonucleotide microarrays have been used to generate comprehensive genomic maps of >10,000 CNVs (53,54). The functional significance, if any, of most of these polymorphic variants is, however, unknown. What is clear, however, is that no single individual genome contains the full complement of functional genes (55), a paradigm shift that strikes at the heart of the concept of a “reference genome” (56).

Deletional polymorphisms are also remarkably frequent in the human genome: a typical individual has been estimated to be hemizygous for some 30–50 deletions >5 kb, spanning >550 kb in total, and encompassing >250 known or predicted genes (57,58). Since such deletions appear to be in linkage disequilibrium with neighboring SNPs, we may surmise that they share a common evolutionary history (59).

Human DNA polymorphisms have proven extremely useful in developing linkage maps, for mapping monogenic and polygenic complex disorders, for determining the origin of aneuploidies and chromosomal

abnormalities, for distinguishing normal from mutant chromosomes in genetic diagnoses, for performing forensic, paternity, and transplantation studies, for studying the evolution of the genome, the loss of heterozygosity in certain malignancies, the detection of uniparental disomy, the instability of the genome in certain tumors, recombination at the level of the genome, the study of allelic expression imbalance, and the development of haplotype maps of the genome. However, in studying the role of a candidate gene in a given disorder, it is imperative to distinguish between pathogenic mutations that cause a clinical phenotype and the polymorphic variability of the normal genome.

### 7.2.2 Nonsense SNPs

The loss of a particular gene/allele is not invariably associated with a readily discernible clinical phenotype (60,61). This assertion is supported by the identification of more than 1000 putative nonsense SNPs (i.e. nonsense mutations that have attained polymorphic frequencies) in human populations (62,63). About half of these nonsense SNPs have been validated by dbSNP (<http://www.ncbi.nlm.nih.gov/projects/SNP>), a process that involves the exclusion of mutations in pseudogenes and of artifacts caused by sequencing errors. *Bona fide* nonsense SNPs are expected either to lead to the synthesis of a truncated protein product or alternatively to the greatly reduced synthesis of the truncated protein product (if the mRNA bearing them is subject to nonsense-mediated mRNA decay (NMD)). Based on the relative locations of the nonsense SNPs and the exon–intron structures of the affected genes, Yamaguchi-Kabata et al. (2008) (64) concluded that 49% of nonsense SNPs would be predicted to elicit NMD, whereas 51% would be predicted to yield truncated proteins. Some of these nonsense SNPs have been found to occur in the homozygous state in normal populations (62), attesting to the likely functional redundancy of the corresponding genes. At the very least, genes harboring nonsense SNPs may be assumed to be only under weak selection (63).

It should be appreciated that nonsense SNPs may even occur in “essential” genes, yet still fail to come to clinical attention (or give rise to a detectable phenotype) if these genes are subject to CNV (see CNVs and copy number mutations below) that masks any deleterious consequences by ensuring an adequate level of gene expression from additional wild-type copies either in *cis* or in *trans*. Thus, CNV might serve to “rescue” the full or partial loss of gene function brought about by the nonsense mutations, thereby accounting for the occurrence of the latter at polymorphic frequencies. Consistent with this postulate, Ng et al. (2008) (63) reported that ~30% of nonsense SNPs occur in genes residing within segmental duplications, a proportion some three-fold larger than that noted for synonymous SNPs. Genes harboring nonsense SNPs were also found to belong to

gene families of higher than average size (63), suggesting that some functional redundancy may exist between paralogous human genes. In support of this idea, Hsiao and Vitkup (2008) (65) reported that those human genes that have a homolog with  $\geq 90\%$  sequence similarity are approximately three times less likely (66) to harbor disease-causing mutations than genes with less closely related homologs. They interpreted their findings in terms of “genetic robustness” against null mutations, with the duplicated sequences providing “back-up” by potentiating the functional compensation/ complementation of homologous genes in the event that they acquire deleterious mutations.

## 7.3 DISEASE-CAUSING MUTATIONS

### 7.3.1 The Nature of Mutation

Figure 7-2 depicts the frequencies of the various mutation types responsible for molecularly characterized human genetic disorders, as recorded in HGMD (<http://www.hgmd.org>) and Refs. (67,68). HGMD records each mutation *once* regardless of the number of independent occurrences of that lesion. Figure 7-2 shows the frequency of the first mutation per disease recorded in MIM (<http://www.ncbi.nlm.nih.gov/Omim> and <http://omim.org/>) and Ref. (69). As of December 2011, HGMD contained some 120,000 different disease-causing mutations and disease-associated/functional polymorphisms in 4411 human genes (Figure 7-2), whereas MIM contained selected examples of allelic variants in 3329 human genes associated with a specific phenotype.

### 7.3.2 Nucleotide Substitutions

Single nucleotide substitutions are the most frequent pathological mutations in the human genome (Figure 7-2). Most of these alterations occur during DNA replication, which is an accurate yet error-prone multistep process. The accuracy of DNA replication depends on the fidelity of the replicative step and the efficiency of the subsequent error correction mechanisms (70). Analysis of more than 7000 missense and nonsense mutations associated with human disease has indicated that the most common nucleotide substitution for T (thymine) is to C (cytosine), for C it is to T, for A (adenine) it is to G (guanine), and for G it is to A (71). Transitions are, therefore, much more common than transversions. Some 61% of the missense and nonsense mutations currently logged in HGMD are transitions (T to C, C to T, A to G, G to A) while 39% are transversions (T to A or G, A to T or C, G to C or T, C to G or A).

Among single nucleotide substitutions, there is one that clearly predominates and represents the most common type of mutational lesion in the human genome: CpG dinucleotides mutate to TpG at a frequency that is about five times higher than mutations in all other

dinucleotides (71–74). This substitution, which when it occurs on one DNA strand generates TG, and on the other, CA (the “CG to TG or CA rule”) represents a major cause of human genetic disease. This phenomenon was first observed in the factor VIII (*F8*) gene in cases of hemophilia A (73), but it was soon noted in the studies of many other genes (75). In hemophilia A, CG to TG or CA mutations account for 46% of point mutations in unrelated patients (76). In the HGMD (68) (<http://www.hgmd.org>), such mutations currently account for ~18% of the total number of missense and nonsense mutations (66). Among CpG dinucleotide mutations, transitions to TG or CA account for ~90% of substitutions. The mechanism of this common type of mutation appears to be methylation-mediated deamination of 5-methylcytosine

(5mC). In eukaryotic genomes, 5mC occurs predominantly in CpG dinucleotides, most of which appear to be methylated (see (77) for review). 5mC then undergoes spontaneous nonenzymatic deamination to form thymine (Figure 7-3). There is a bias in terms of the origin of CpG to TpG mutations: most occur in male germ cells (the male:female ratio is 7:1). One reason for this may be that sperm DNA is heavily methylated, whereas oocyte DNA is comparatively undermethylated (78). Another reason may be the considerably higher number of germline cell divisions in males as compared to females (79).

Cytosine methylation also occurs in the context of CpNpG sites (80). If we assume not only that CpNpG methylation occurs in the germline but also that 5mC deamination can occur within a CpNpG context, then it

**FIGURE 7-2** Spectrum of different types of human disease-causing mutations and disease-associated/functional polymorphisms logged in the HGMD as of December 2011.

**FIGURE 7-3** Schematic representation of cytosine, 5'-methylcytosine and thymine, and the chemical events involved in the mutational transformation of cytosine to thymine.

follows that methylated CpHpG sites are also very likely to constitute mutation hotspots causing human inherited disease. Initial evidence that this might indeed be the case came from the observation that disproportionately high numbers of C>T and G>A transitions occur at CpNpG sites in studies of the human genes, *NF1* (81) and *BRCA1* (82). Further, ~9.9% of 54,625 missense and nonsense mutations from 2113 genes causing inherited disease (HGMD) are C>T and G>A transitions located within CpNpG trinucleotides, approximately twofold higher proportion than would have been expected by chance alone (66). Some 5% of missense or nonsense mutations causing human inherited disease may, therefore, be attributable to methylation-mediated deamination of 5 mC within a CpNpG context.

In a recent analysis, the average direct estimate of the combined rate of all mutations was  $1.8 \times 10^{-8}$  per nucleotide per generation (83). Single nucleotide substitutions were found to be ~25 times more common than all other mutations, while deletions were ~3 times more common than insertions; complex mutations were very rare and the CpG context was found to increase substitution rates by an order of magnitude (84). Rates of different kinds of mutations were also found to be strongly correlated across different loci (84).

It has been estimated that ~20% of new missense mutations in humans result in a loss of function, whereas 53% have mildly deleterious effects, and 27% are effectively neutral with respect to phenotype (85). These estimates have received independent support, at least qualitatively, from a study of human coding SNPs by Boyko et al. (86), who predicted that 27–29% of missense mutations would be neutral or near neutral, 30–42% would be moderately deleterious, with most of the rest (i.e. 29–43%) being highly deleterious or lethal, and by Eyre-Walker et al. (87) who estimated that >50% of mutations would be likely to exert only a mild effect on the phenotype.

A recent study using human osteosarcoma cell lines has shown that noncanonical (non-B) DNA conformations are capable of increasing the overall spectrum of single base-pair substitutions in a reporter gene in *cis* by exposing those DNA sequences to oxidative damage (88). In this study, the spectrum of single base-pair substitutions was shown to be indistinguishable from that induced by other conditions known to lead to an hyperoxidative state (such as WRN deficiency and lung tumorigenesis), an observation which lends support to a model whereby DNA bases become oxidized, followed by the transfer of their oxidized state (“hole migration”) to target neighboring bases. If these observations are eventually found to be relevant in the context of “natural” chromatin during meiosis, then the impact of non-B DNA conformations on human inherited disease, both with respect to single base-pair substitutions and gross rearrangements (see Section 7.3.6), could be quite significant. Further, since non-B DNA structures can

interfere with DNA replication and repair, and may serve to increase mutation frequencies in generalized fashion, they have the potential to serve as a unifying concept in studies of mutational mechanisms underlying human inherited disease.

### 7.3.3 Synonymous Nucleotide Substitutions

Synonymous (“silent”) mutations, although not altering the amino acid sequence of the encoded protein directly, can still influence splicing accuracy or efficiency (89–94). It has become increasingly clear that apparently silent SNPs may also become distinctly “audible” in the context of mRNA stability or even protein structure and function. Thus, three common haplotypes of the human *COMT* gene, which differ in terms of two synonymous and one nonsynonymous substitution, confer differences in *COMT* enzymatic activity and pain sensitivity (95,96). The major *COMT* haplotypes differed with respect to the stability of the *COMT* mRNA local stem-loop structures, the most stable being associated with the lowest levels of *COMT* protein and enzymatic activity (95). In similar vein, synonymous SNPs in the *ABCB1* gene have been shown to alter *ABCB1* protein structure and activity (97), possibly by changing the timing of protein folding following extended ribosomal pause times at rare codons (98). Finally, it should be understood that although the deleteriousness of the average synonymous mutation is always likely to be less than that of a nonsynonymous (missense) mutation (86), the higher prevalence of synonymous mutations means that they may actually make a significantly greater contribution to the phenotype than nonsynonymous mutations (99).

### 7.3.4 Micro-Deletions and Micro-Insertions

Deletions or insertions of a few nucleotides are also fairly common as a cause of human inherited disease. Most of these are less than 20 base pairs (bp) in length. Indeed, the majority of micro-deletions involve <5 nucleotides. In HGMD, the deletion of 1 bp accounts for 48% of small deletions while an additional 30% involve two or three nucleotides. The majority of micro-deletions recorded (78%) result in an alteration of the reading frame. Most micro-deletions occur in regions that contain direct repeats of 2 bp or more. The most common length of direct repeat is 3 bp (48% of direct repeats associated with short deletions (74)). The most plausible mechanism for small deletions mediated by the presence of direct repeats is the slipped mispairing model (100) (Figure 7-4). In addition, deletions of one or a few nucleotides frequently occur in runs of the same nucleotide, for example, a poly(T) region (101). Finally, inverted repeats and “symmetric elements” are also frequently found in the immediate vicinity of micro-deletions (102,103). Krawczak and Cooper (104) identified a

consensus sequence—TG(A/G)(A/G)(G/T)(A/C)—which they claimed to represent a deletion hotspot.

Micro-insertions (again up to 20 nucleotides) are rarer than micro-deletions; thus, in HGMD there are three times as many micro-deletions as micro-insertions

**FIGURE 7-4** Schematic representation of the slipped mispairing model for deletions and insertions during DNA replication.

(Figure 7-2). Nearly half of these involve the insertion of only one nucleotide (Figure 7-5). As is the case with micro-deletions, most micro-insertions lead to alterations of the reading frame and are located in regions containing direct or inverted repeats or runs of the same nucleotide. Details of possible mechanisms of generation during replication can be found in (105). However, there are as-yet insufficient data available to estimate the frequency ratio of micro-insertions or micro-deletions in male or female germ cells. In the case of such lesions in factor VIII (*F8*) gene, 56% of micro-deletions/-insertions have been reported to occur in DNA regions harboring direct repeats or runs of the same nucleotide (76).

HGMD data (3767 micro-deletions and 1960 micro-insertions) were used to perform a meta-analysis of micro-deletions and micro-insertions causing inherited disease, both defined as involving  $\leq 20$ bp DNA (106). A positive correlation was noted between the micro-deletion and micro-insertion frequencies for 564 genes in which both micro-deletions and micro-insertions have been reported. This is consistent with the view

### HGMD Small Deletions and Insertions (1-Dec-11)

**FIGURE 7-5** Size distribution of short (<20 bp) pathogenic human gene deletions and insertions (HGMD; <http://www.hgmd.org>; 5 January 2007).

that the propensity of a given gene/sequence to undergo micro-deletion is related to its propensity to undergo micro-insertion. While micro-deletions and micro-insertions of 1 bp constitute, respectively, 48% and 66% of the corresponding totals, the relative frequency of the remaining lesions correlates negatively with the length of the DNA sequence deleted or inserted. Many micro-deletions and micro-insertions of >1 bp are potentially explicable in terms of slippage mutagenesis, involving the addition or removal of one copy of a mono-, di-, or trinucleotide tandem repeat. The frequency of in-frame 3 bp and 6 bp micro-insertions and micro-deletions was, however, found to be significantly lower than that of mutations of other lengths, suggesting that some of these in-frame lesions may not have come to clinical attention. Various sequence motifs were found to be overrepresented in the vicinity of both micro-insertions and micro-deletions, including the heptanucleotide CCCCCTG that shares homology with the complement of the 8-bp human minisatellite conserved sequence/chi-like element (GCWGGWGG). The “indel hotspot” GTAAGT (and its complement ACTTAC) were also found to be overrepresented in the vicinity of both micro-insertions and micro-deletions, thereby providing a first example of a mutational hotspot that is common to different types of gene lesions. Other motifs overrepresented in the vicinity of micro-deletions and micro-insertions included DNA polymerase pause sites and topoisomerase cleavage sites. Several novel micro-deletion/micro-insertion hotspots were noted and some of these exhibited sufficient similarity to one another to justify terming them “super-hotspot” motifs. Analysis of DNA sequence complexity also demonstrated that a combination of slipped mispairing mediated by direct repeats, and secondary structure formation promoted by symmetric elements, can account for the majority of micro-deletions and micro-insertions. Thus, micro-insertions and micro-deletions exhibit strong similarities in terms of the characteristics of their flanking DNA sequences, implying that they are generated by very similar underlying mechanisms.

A similar analysis on micro-deletions and micro-insertions in 19 human genes presented evidence for an elevated micro-deletion rate at YYYYTG and an elevated micro-insertion rate at TACCRC and ATMMGCC (107). These authors also found that ~45% of micro-deletions led to the removal of a repeated sequence, an event they termed “deduplication” in order to highlight the identity of the deleted sequence and the sequence abutting the site of deletion.

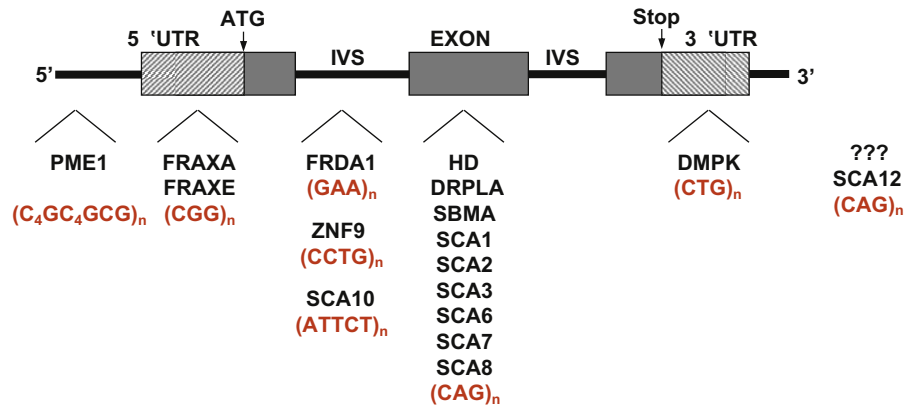

### 7.3.5 Expansion/Copy Number Variation of Trinucleotide (and Other) Repeat Sequences

Another mechanism of human gene mutation causing hereditary disease is the instability of repeat (mainly trinucleotide) sequences and their expansion in affected

genes (108–110). A growing number of repeat expansion disorders (in excess of 66 are now recorded in HGMD), the majority of which involve neuromuscular tissue, have been found to be due to, or associated with, the expansion of repeat sequences; of these, 53 are expansions of triplet repeats. The first such disease was fragile X, a common cause of male mental retardation, which mapped to chromosome Xq27.3. Some examples of these disorders include Huntington disease, myotonic dystrophy, spinobulbar muscular atrophy, spinocerebellar ataxia 1, spinocerebellar ataxia 3 or Machado–Joseph disease, the fragile E site, and dentatorubral pallidolysian atrophy. Genetic “anticipation” (the earlier onset and increasingly severe phenotype in successive generations) is a common phenomenon in these disorders (111). The trinucleotide involved is usually either CAG or CGG but occasionally CTG, GCG, or GAA. It can be located in the 5′ untranslated region (UTR) as in the case of the *FMR1* gene underlying fragile X, within the coding region (as in Huntington disease, spinocerebellar ataxia 1 (SCA1), SCA3, and Kennedy disease) where it encodes poly(Gln), in an intron as in Friedreich ataxia (*FXN*) and myotonic dystrophy type 2 (*ZNF9*), or in the 3′ UTR as in myotonic dystrophy type 1 (*DMPK*) (Figure 7-6). The expansion of the triplet repeat either prevents the expression of the associated gene (112), results in a dominant gain-of-function mutation mediated by the longer poly(Gln) peptide (113), or alters the RNA processing of other genes (114,115).

Trinucleotide repeats are usually polymorphic in human populations. Rarely, however, the number of trinucleotide repeats lies within a high risk category that is termed a “premutation.” In such a case, the premutation exhibits a high probability of further expansion (instability) to yield disease-related alleles (“full mutation”). In fragile X, for example, the normal polymorphic alleles of the CGG repeat contain between 10 and 50 triplets, the premutation between 50 and 200 triplets, and the full mutation more than 200 triplets (116). Expansion of premutations to full mutations only occurs during female meiotic transmission. The probability of repeat expansion correlates with repeat copy number in the premutated allele. Since the premutation must precede the appearance of a full mutation, all mothers of affected children carry either a full mutation or a premutation (116). Premutation alleles may also be associated with late-onset movement disorders and premature ovarian failure (117,118).

The precise mechanism of repeat expansion is unclear although it is known that DNA polymerase progression is blocked by CTG and CGG repeats and the resultant idling of the polymerase could serve to catalyse slippage leading to repeat expansion (119). In the case of SCA1, interruption of the CAG repeat with a CAT unit is associated with more stable trinucleotide repeat (120). More details of these “dynamic mutations” can be found in the appropriate sections covering individual disorders, and in Ref. (121). Short expansions of GCG trinucleotide codons encoding Ala have been observed in

### Selected Repeat Expansions in Human Disorders

**FIGURE 7-6** Location of the repeat expansion in selected human disorders.

the *HOXD13* gene causing dominant polydactyly, and in the *PABP2* gene causing oculopharyngeal muscular dystrophy (122,123). These mutations may be due to unequal crossing-over rather than polymerase slippage. Generally speaking, it is likely that repeat instability is a consequence of the resolution of unusual secondary structure intermediates during DNA replication, repair, and recombination (124).

A repeat expansion of 12 nucleotides (CCCCGCCCGCG) in the 5' flanking region of the *CSTB* gene causes one form of the recessive progressive myoclonus epilepsy type 1 (EPM1) (125). This indicates that repeat sequences other than trinucleotides can expand and cause human disorders. This particular expansion silences the *CSTB* gene, probably because it alters the spacing of transcription factor binding sites from each other and/or the transcriptional initiation site (126).

A tetranucleotide repeat expansion (CCTG)<sub>n</sub> in intron 1 of the *ZNF9* gene causes myotonic dystrophy type 2 (115). This expansion can be between 75 and 11,000 repeats in length. The expansion of the pentanucleotide repeat (ATTCT)<sub>n</sub> is responsible for the phenotype of spinocerebellar ataxia 10 (SCA10). The expansion occurs in intron 9 of the *SCA10* gene and can be up to 22.5 kb in length (127). Expansions of even longer repeats have been reported. In Usher syndrome type 1C, for example, there is an expansion of a 45 bp VNTR in intron 5 of the *USH1C* gene (nine tandem repeats instead of the usual less than six such repeats); this expansion has been predicted to inhibit the transcription of the gene (128). There are also cases in which a large repeat expansion is not associated with a particular phenotype, for example, the expansion of an AT-rich 33-mer repeat in the dictamycin-sensitive fragile site 16B (129).

### 7.3.6 Mechanisms of Gross Genomic Rearrangement

Structural variation in the human genome is characterized by a number of different types of gross rearrangements

including deletions, duplications, insertions (termed CNVs) as well as inversions, and translocations. Four major mutational mechanisms account for these SVs: nonallelic homologous recombination (NAHR), nonhomologous end joining (NHEJ), replication-based mechanisms, and L1-retrotransposition (53,54,130).

**NAHR:** Sequence analysis of the breakpoints of 1054 SVs identified in the genomes of 17 healthy human individuals revealed that NAHR accounts for 22% of insertions and deletions as well as 69% of inversions (130). The majority of these SVs are likely to represent neutral polymorphisms but ~1% may be disease associated. However, some apparently neutral SVs appear to predispose to further structural rearrangements, such as deletions and duplications, which then in turn give rise to disease (131–135). Thus, for example, heterozygosity for the ~970 kb inversion polymorphism of the *MAPT* locus at 17q21.3 predisposes to the NAHR events that underlie the 17q21.31 micro-deletion syndrome (136,137). It may be that inversion heterozygosity perturbs the pairing of homologous chromosomes during meiosis, which then promotes interchromosomal NAHR between the inversion-flanking low copy repeats (LCRs), thereby giving rise to the 17q21.3 micro-deletion.

During meiosis, NAHR between sequences that are nonallelic (i.e. paralogous) can result in recurrent deletions and duplications that cause specific genomic disorders. Liu et al. (138) studied two patient cohorts with reciprocal genomic disorders localized to chromosome 17p11.2: the deletion-associated Smith–Magenis syndrome and the duplication-associated Potocki–Lupski syndrome. They reported that complex rearrangements (those with more than one breakpoint) were more prevalent in copy number gains (17.7%) than in copy number losses (2.3%), an observation which supports a role for replicative mechanisms in the formation of complex rearrangements. With respect to the NAHR-mediated recurrent rearrangements, the crossover frequency was found to be positively associated with the flanking LCR length and inversely influenced by the inter-LCR distance. It

would, therefore, appear that the probability of ectopic chromosome synapsis increases with increasing LCR length, with ectopic synapsis being a prerequisite for ectopic crossing-over.

Recent findings also indicate that NAHR represents a major mechanism underlying unbalanced recurrent translocations, which are mediated by either interchromosomal LCRs or segmental duplications located on nonhomologous chromosomes (139).

**NHEJ:** The defining characteristic of NHEJ is the ligation of double-strand break (DSB) ends without the requirement for extensive homology, in stark contrast to the situation pertaining with homologous recombination. The presence of terminal microhomologies (typically 1–3 bp) facilitates NHEJ but this appears not to be an absolute requirement; only 30–50% of all SVs in the human genome have originated through microhomology-mediated NHEJ events (53,140).

Although some NHEJ events would have resulted from the repair of DSBs that originated quasi-randomly, there are also many well-documented cases in which the locations of the NHEJ-initiating DSBs appear to be highly dependent on the local DNA sequence environment. The role of the local DNA sequence context in generating NHEJ-mediated germline mutations is exemplified by the constitutional t (11;22)(q23;q11), the most common type of recurrent non-Robertsonian translocation in humans (141,142). The breakpoint sequences of both chromosomes are characterized by several hundred base pairs of inverted AT-rich repeats; similar sequences have also been identified at the breakpoints of other nonrecurrent translocations (143). It would appear that the NHEJ of two ends from different DSBs requires those ends to be physically located in the immediate vicinity. Indeed, DSBs tend to undergo translocations with those chromosomes with which they share nuclear space (144). This provides strong support for the “contact-first” hypothesis, which proposes that interactions between different DSBs can only take place if they are colocalized at the time of DNA damage (145). Consistent with this hypothesis, close spatial proximity has been observed between several frequent translocation partners (146,147).

A number of recombination-predisposing motifs and non-B DNA-forming sequences have been found to be overrepresented at NHEJ breakpoints, indicative of the sequence-directed nature of many NHEJ-mediated rearrangements (148,149). It has also been observed that at least one of the breakpoints of NHEJ-mediated rearrangements is often located within repetitive elements (such as LTRs, LINE or *Alu* elements) and sequence motifs capable of causing DSBs have been frequently identified in the vicinity of the breakpoints of these NHEJ-mediated rearrangements (150). Importantly, the breakpoints of many nonrecurrent CNVs mediated by NHEJ map to LCRs, suggesting that LCRs can promote genomic instability by inducing certain chromatin secondary structures.

**Replication-based mechanisms:** Replication slippage or template switching during replication account for both small and large deletions and duplications with terminal microhomologies. Recently, relevant replication-based models including serial replication slippage (SRS) (151–153), fork stalling and template switching (FoSTes) (154), and microhomology-mediated break-induced replication (MMBIR) (155), which were collectively termed microhomology-mediated replication-dependent recombination by Chen et al. (156), have been used to explain the generation of a diverse range of complex genomic rearrangements (154,157).

DNA replication stalling-induced chromosome breakage has also been found to be an important mechanism causing deletions at chromosomal ends. Different types of telomeric deletions have been described (158): type A terminal deletions are formed by chromosomal ends that are stabilized by the capture of a telomere from another source, whereas type B deletions are actually interstitial deletions toward the chromosomal ends. By contrast, type C deletions describe the process by which chromosomal ends are stabilized by telomere healing, namely the telomerase-dependent de novo addition of telomeres at non-telomeric sites. Terminal deletions associated with inverted duplications (159) can be classified as either type A or type C. Recently, Hannes et al. (160) succeeded in cloning the breakpoints of nine chromosome 4p terminal deletions. All nine cases were shown to be type C terminal deletions. Bioinformatics analysis of the breakpoint-flanking regions involved in these 9 cases, together with 12 previously fully characterized type C terminal deletions, led to the realization that there is an enrichment in secondary structure-forming sequences and replication stalling site motifs in these regions as compared with a randomly selected sequence dataset (160).

Certain sequence features, such as microsatellites and transposon-rich regions, can serve to induce replication stalling, thereby acting as potential sources of genome instability (161,162). On this basis, Koszul et al. (163) proposed a two-step mechanism to account for the generation of large segmental duplications: “First, a replication fork pauses and collapses generating a chromosome breakage. Second, the double-strand break can be processed into a new replication fork either intra- or inter-molecularly by a break-induced replication-like mechanism that does not necessarily need a long sequence homology.” It was this “microhomology-dependent BIR” model that was subsequently deployed to explain disease-causing copy number mutations. In MMBIR, replication ends with the engagement of a misaligned template instead of reannealing to its original template; the synthesis of the second strand then follows the synthesis of the first (reviewed in (156)). In practice, mutations due to SRS/FoSTes are often indistinguishable from those due to MMBIR. Indeed, the two terms have sometimes been used interchangeably (164,165).

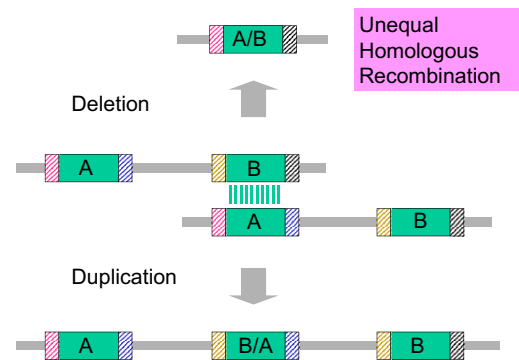

Ankala et al. (166) have recently proposed another mechanism, the aberrant firing of replication origins, to explain a number of complex lesions in a series of 62 intragenic nonrecurrent rearrangements within various genes (mainly in the *DMD* gene). While repetitive sequence elements were noted in only four individual cases, microhomologies (2–10 bp) were observed at breakpoint junctions in 56% of the cases studied; further, insertions ranging from 1 to 48 bp were noted in 16 of the 62 cases. The sequence proximal to the breakpoints in six individual Duchenne muscular dystrophy (DMD) cases was characterized by tandem repetitions of short segments (5–20 bp). The repeated replication of template sequences proximal to the mapped deletion breakpoints was taken as evidence of attempts by the replication machinery to bypass a stalled replication fork. This mutational mechanism, based on the replication rescue model originally suggested by Doksanı et al. (167), constitutes a novel type of template slippage event. Indeed, it can be seen that microhomologies at CNV breakpoints may be attributed to microhomology-mediated end joining (MMEJ), a replication repair mechanism, rather than to a recombination-based mechanism.

### 7.3.7 Gross Deletions

Gross deletions are common causes of certain disorders and rare in others. In most of the X-linked disorders, for example, large deletions account for about 5% of molecular defects. In other disorders, however, such as steroid sulfatase deficiency, large deletions of the *STS* gene account for 84% of patients (168). The same is true for disorders such as DMD, growth hormone deficiency, and  $\alpha$ -thalassemia (169–171).

A considerable number of large deletions are probably generated by mispairing of homologous sequences and unequal recombination (Figure 7-7). One of the best examples of homologous unequal recombination is the case of  $\alpha$ -globin genes on chromosome 16p. As a result of a recent evolutionary duplication of the  $\alpha$ -globin genes, extensive regions of sequence homology exist between the two closely linked  $\alpha$ -genes. Unequal crossover results in either the deletion of one  $\alpha$ -gene or the creation of a fusion hybrid gene (172). The reciprocal product chromosomes carry three  $\alpha$ -genes and are not associated with a clinical phenotype (173). Another example of a fusion gene resulting from an unequal crossover is the case of Hemoglobin Lepore characterized by a hybrid gene between the  $\delta$ - and  $\beta$ -globin genes on chromosome 11p (174). In the case of steroid sulfatase deficiency, the deletion can be as large as 1 Mb (175). In Kallmann syndrome, translocation can occur as a result of unequal mispairing of X and Y homologous sequences (176).

A number of common genetic disorders are due to large deletions (or duplications) caused by unequal crossing-over of homologous sequences. Figure 7-8 depicts various examples that include a 1.5 Mb deletion of

**FIGURE 7-7** Homologous unequal recombination between similar regions of sequences A and B. The recombination events cause either deletions or duplications. In the case of a deletion, a hybrid sequence is generated with the first part from sequence A and the second from sequence B. The middle sequence in the duplication product is also a hybrid sequence; the first part is from sequence B and the second from sequence A.

17p12 in hereditary neuropathy with liability to pressure palsies (HNPP) (177), deletion of 1.5 Mb of 17q11.2 in neurofibromatosis type 1 (178), deletion of 1.6 Mb of 7q11.23 in Williams syndrome (179), deletion of 5 Mb of 17p11.2 in Smith–Magenis syndrome (180), deletion of either 3 Mb or more rarely 1.5 Mb of 22q11 in DiGeorge and velo-cardio-facial syndromes (181,182), and 4 Mb deletions of 15q in Prader–Willi and Angelman syndromes (183). A recurrent deletion of ~0.5 Mb of 17q21.3, which may be mediated by a common inversion polymorphism, has also been described (83,184–186). For a review of chromosomal “duplicons,” the LCRs that mediate deletions and duplications, see Ref. (187). It has been estimated that ~5% of the human genome is duplicated either intra- or interchromosomally (188). The large deletions or duplications (see below) due to duplicon crossover are also termed “genomic disorders.” A recent review of such genomic disorders may be found in Ref. (189).

In many cases of large deletion, homologous unequal crossover occurs between repetitive elements such as *Alu* sequences (190). The *Alu* repeat is the most abundant repetitive element with about  $1.5 \times 10^6$  copies in the human genome (191,192). The element is about 300 bp in length and consists of two similar regions separated by a short A-rich region. Unequal crossover can occur between *Alu* sequences oriented in either the opposite or the same direction. In addition, unequal crossings over have been noted between *Alu* elements and nonrepetitive DNA sequences without homology to *Alus*. The best examples of *Alu*-*Alu* recombination occur in the genes encoding the low-density lipoprotein receptor (*LDLR*) which underlies familial hypercholesterolemia, and complement component 1 inhibitor (*C1I*; (193,194)). All but one of the breakpoints associated with *LDLR* gene deletions occur within *Alu* repeats. By contrast, deletions in other *Alu*-rich genes (e.g. *GLA1*) do not necessarily involve *Alu* repetitive elements (195). This

notwithstanding, *Alu*-mediated recombination between nonallelic *Alu* sequences is a fairly frequent cause of gene deletion causing human genetic disease (196–205). It should be appreciated that the importance of *Alu* sequences in the context of mediating genomic deletions does not lie simply with their sheer abundance; *Alu* elements also possess inherent recombination–predisposing properties (206).

Nonhomologous (illegitimate) recombination occurs between two DNA sites that share minimal sequence homology of a few base pairs. This type of recombination during meiosis or alternatively, slipped mispairing during DNA replication mediated by short (2–8) nucleotide direct repeats flanking the deletions is a common finding in many instances of large gene deletions (207). Such deletions have been studied, for example, in hemophilia A; a compilation of 46 junctions from large deletions revealed that about 50% shared 2- to 6-bp homology at the breakpoint junction, as compared with only 17% in which the deletion was due to *Alu*–*Alu* recombination (208). Similar results have been reported from the intron 7 deletion hotspot in the *DMD* gene; 8/9 deletion breakpoints examined were found to be flanked by DNA sequences with minimal homology (209).

It has also been proposed that alternative DNA conformations may trigger genomic rearrangements through

recombination–repair activities. Distance measurements have indicated the significant proximity of alternating purine–pyrimidine and oligo(purine–pyrimidine) tracts to breakpoint junctions in 222 gross deletions and translocations, respectively, involved in human diseases. In 11 deletions analyzed, breakpoints were explicable by non-B DNA structure formation (210).

The Gross Rearrangement Breakpoint Database (GRaBD; <http://www.uwcm.ac.uk/uwcm/mg/grabd/>) was established primarily for the analysis of the sequence context of translocation and deletion breakpoints in a search for characteristics that might have rendered these sequences prone to rearrangement (211). GRaBD, which contains 397 germline and somatic DNA breakpoint junction sequences derived from 219 different rearrangements underlying human inherited disease and cancer, represents a large but not comprehensive collection of sequenced gross gene rearrangement breakpoint junctions. Analysis of these breakpoints has extended our understanding of illegitimate recombination by highlighting the importance of secondary structure formation between single-stranded DNA ends at breakpoint junctions. For example, potential secondary structure was noted between the 5′ flanking sequence of the first breakpoint and the 3′ flanking sequence of the second breakpoint in 49% of rearrangements, and between the

**FIGURE 7-8** Genes, duplons, and diseases. Unequal crossover between homologous sequences (duplons) produce either deletions or duplications of the DNA between the duplons. The duplons are shown by arrows or by clear boxes. Genes included in the duplications/deletions are shown as dark boxes. STSD, steroid sulfatase deficiency; CMT1A, Charcot-Marie-Tooth type A1; HNPP, hereditary neuropathy with liability to pressure palsies; NF1, neurofibromatosis 1; HemoA, hemophilia A; WS, Williams syndrome; SMS, Smith–Magenis syndrome; VCFS, Velo–cardio–facial syndrome; PWS, Prader–Willi syndrome; AS, Angelman syndrome.

5' flanking sequence of the second breakpoint and the 3' flanking sequence of the first breakpoint in 36% of rearrangements (149). In addition, deletion breakpoints were found to be AT-rich whereas translocation breakpoints were GC-rich. Alternating purine-pyrimidine sequences were found to be significantly overrepresented in the vicinity of deletion breakpoints while polypyrimidine tracts were overrepresented at translocation breakpoints (148).

Finally, several examples of pathogenic large genomic deletions caused by the prior L1-mediated insertion of L1 (212,213), *Alu* (214,215), or SVA (216) insertions (see below) have been reported, as well as the first cases of L1-driven pseudogene insertion causing human genetic disease (217,218).

### 7.3.8 Large Retrotranspositional Insertions

A less common but nevertheless still fascinating mechanism of human gene mutation is the de novo insertion of repetitive elements via retrotransposition. The phenomenon was first observed in humans in the factor VIII (*F8*) gene in two unrelated de novo cases of severe hemophilia A (219). Truncated LINE (long interspersed) repetitive elements were introduced into exon 14 of the factor VIII (*F8*) gene where they caused disruption of the reading frame. The inserted elements contained a poly(A) tract and caused a target site duplication of more than 12 nucleotides. Further analysis of these insertions revealed that, in one case, the inserted element was an exact but truncated copy of a full-length LINE element with open reading frames (ORFs) found at chromosome 22q11 (220). The master source gene produces an mRNA that is probably

reverse transcribed (possibly via a reverse transcriptase encoded by itself) and the double-stranded nucleic acid is then reinserted into an A-rich region of the genome (Figure 7-9). LINEs probably integrate into genomic DNA by a process called target-primed reverse transcription (221). The proposed mechanism of LINE retrotransposition is as follows: An active LINE is transcribed in the nucleus and is subsequently transported to, and translated in, the cytoplasm. The two LINE-encoded proteins, ORF1 and ORF2, complex with LINE transcripts in ribonucleoprotein particles. The complexes are then transported to recipient DNA sequences where target-primed reverse transcription occurs. The new, integrated LINE copy is usually truncated at its 5' end. Over evolutionary time, L1s have shaped mammalian genomes through a number of different mechanisms. First, they have greatly expanded the genome both by their own retrotransposition and by providing the machinery necessary for the retrotransposition of other mobile elements, such as *Alu* sequences or SVA elements (153). Second, they have shuffled non-L1 sequence throughout the genome by a process termed transduction. Accidents of retrotransposition can cause disease and a number of such insertions have been reported to date (221,222). It is noteworthy that insertions of these elements within introns of genes or flanking regions are probably not associated with disease, but instead represent rare, private polymorphisms (223).

Similar retrotranspositions that involve members of the *Alu* sequence family have also been reported in several genes (examples include *Alu* insertions into the *NF1* gene causing type 1 neurofibromatosis, into the factor IX (*F9*) gene causing hemophilia B, and into the cholinesterase (*BCHE*) gene in a case of acholinesterasemia;

**FIGURE 7-9** Schematic representation of LINE retrotransposition. A master retrotransposon (full length LINE) from one chromosomal location is transcribed to mRNA; then reverse transcribed to double-stranded DNA and inserted into an adenine-rich region of another chromosomal location. The transposon has a poly(A) tail and produces a target site duplication.

(224–226)). It is likely that LINEs provide the molecular machinery necessary for the retrotransposition of *Alus*. One study using mutation analysis of the *F9* gene has estimated the frequency of retrotransposition to be such that it occurs somewhere in the genome of about 1 in every 17 children born (227).

Some 17% of a collection of gross insertions, all  $\geq 276$  bp in length, were due to LINE-1 (L1) retrotransposition involving different types of elements (L1 *trans*-driven *Alu*, L1 direct, and L1 *trans*-driven SVA) (153). A meta-analysis of 48 recent L1-mediated retrotranspositional events known to have caused human genetic disease revealed that 26 were L1 *trans*-driven *Alu* insertions, 15 were direct L1 insertions, 4 were L1 *trans*-driven SVA insertions, and 3 were associated with simple poly(A) insertions (228). The systematic study of these lesions, when combined with previous in vitro and genome-wide analyses, allowed several conclusions regarding L1-mediated retrotransposition to be drawn: (a) ~25% of L1 insertions are associated with the 3' transduction of adjacent genomic sequences, (b) ~25% of the new L1 inserts are full-length, (c) poly(A) tail length correlates inversely with the age of the element, and (d) the length of target site duplication in vivo is rarely longer than 20 bp. This analysis also suggested that some 10% of L1-mediated retrotranspositional events are associated with significant genomic deletions in humans.

Interestingly, Chen et al. (229) reported an indel in the *CFTR* gene that involved the insertion of a short 41 bp sequence with partial homology to a retrotranspositionally competent LINE-1 element. These authors dubbed such insertions of ultra-short LINE-1 elements “hyphen elements.”

Several instances of the clustering of pathogenic L1-mediated insertion events have also been observed. Thus, three independent *Alu* insertions have been found to be integrated into a 104 bp region of the *FGFR2* gene (230,231), two independent L1 insertions have been reported to have inserted into an 89 bp region of exon 44 of the dystrophin (*DMD*) gene (232,233), while six different insertions were found in a 1.5 kb region of the *NF1* gene (234). It should also be noted that independent L1-retrotransposition elements can integrate at precisely the same chromosomal sites. Thus, two markedly different *Alu* Ya5a2 elements became integrated at precisely the same site in the *F9* gene causing severe hemophilia B (226,235), whereas an SVA element and an *Alu* sequence were inserted at the same site within the coding region of the *BTK* gene (236). These observations are consistent with some genomic locations being exquisitely prone to L1-retrotransposition (228).

### 7.3.9 Large Insertion of Repetitive and Other Elements

The insertion of non-retrotransposons, namely beta-satellite repeats, has been observed in the human genome.

The insertion of 18 copies of the 68 bp monomer of the beta-satellite repeat in exon 11 of the *TMPRSS3* gene on chromosome 21 caused one form of recessive non-syndromic deafness DFNB10 (237). This may have been mediated by invasion of the genomic DNA by a small polydispersed circular DNA.

A patient with a sporadic case of Pallister–Hall syndrome has been shown to have experienced a de novo nucleic acid transfer from the mitochondrial to the nuclear genome. This mutation, a 72 bp insertion into exon 14 of the *GLI3* gene, creates a premature stop codon and predicts a truncated protein product. Both the mechanism and the cause of the mitochondrial-nuclear transfer are however unknown (238). Further examples of pathological mitochondrial-nuclear sequence transfers have been subsequently identified in the *USH1C* gene (153) and the *PAFAH1B1* gene (Millar et al. 2010).

Gross insertions ( $>20$  bp) comprise  $<1\%$  of disease-causing mutations. In an attempt to study these insertions in a systematic way, 158 gross insertions ranging in size between 21 bp and ~10 kb were identified from the HGMD; their study has revealed extensive diversity in terms of the nature of the inserted DNA sequence and has provided new insights into the underlying mutational mechanisms (153). Some 70% of gross insertions were found to represent sequence duplications of different types (tandem, partial tandem, or complex). In the context of a 26 bp insertion into the *ERCC6* gene, the authors also speculated as to whether they had found evidence for another mechanism of human genetic disease, involving the possible capture of DNA oligonucleotides (153).

### 7.3.10 Inversions

The most common inversion found to date is that associated with the factor VIII (*F8*) gene, which occurs via intrachromosomal recombination mediated by a 9.5 kb sequence that is repeated three times in the last megabase of Xqter; once in intron 22 of the *F8* gene and twice about 400 kb telomeric to the first (239,240) (Figure 7-10). Most inversions, which are high frequency independent recurring events, involve the distal sequence. The vast majority of inversions occur in male germ cells (241), perhaps because intrachromosomal recombination is inhibited by the presence of homologous X chromosomes (the male:female ratio was estimated to be about 300:1). Almost all mothers of inversion hemophilia A cases are carriers of the abnormality. DNA diagnosis of the molecular lesion in severe hemophilia A has been greatly facilitated by the frequent occurrence of this common inversion of the *F8* gene (45% of individuals with severe hemophilia A). The frequency of de novo *F8* gene inversion has been estimated to be  $7.2 \times 10^{-6}$  per gamete per generation. Another example of inversion has been described in the *IDS* gene (also on Xq) in about 13% of cases of

**FIGURE 7-10** Common inversion of the factor VIII (*F8*) gene in severe hemophilia A. (A) Schematic representation of the most distal 1 Mb of Xq. Regions  $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$  represent 9.5 kb highly homologous DNA elements. The orientations of these sequences are shown by arrows. (B) Intrachromosomal recombination between elements  $\alpha_1$  and  $\alpha_3$ . (C) The crossover results in the inversion of exons 1–22 of the *F8* gene.

Hunter syndrome (242). Inversions of DNA sequences have also been reported in the  $\beta$ -globin gene cluster on 11p and in the *APOA1-APOC3-APOA4* gene cluster on 11q (243,244).

A meta-analysis of inversions of  $\geq 5$  bp but  $< 1$  kb has been performed by Chen et al. (152). Of the 21 mutations studied, 19 were found to be compatible with a model of intrachromosomal serial replication slippage in *trans* (SRStrans) mediated by short inverted repeats. Eighteen (one simple inversion, six inversions involving sequence replacement by upstream or downstream sequence (DSS), five inversions involving the partial reinsertion of removed sequence, and six inversions that occurred in a more complicated context) of these were found to be consistent with either two steps of intrachromosomal SRStrans or a combination of replication slippage in *cis* plus intrachromosomal SRStrans. The remaining lesion, a 31 kb segmental duplication associated with a small inversion in the *SLC3A1* gene, was explicable in terms of a modified SRS model incorporating the concept of “break-induced replication.” This study has, therefore, lent broad support to the idea that intrachromosomal SRStrans can account for a variety of complex gene rearrangements involving inversions.

### 7.3.11 Duplications

Duplications of whole genes or exons have contributed very significantly to the evolution of the human genome (47). Indeed, most gene clusters (e.g.  $\beta$ -globin, growth hormone, Hox) owe their origin to gene duplications that have occurred during vertebrate evolution. Furthermore, the presence of similar domains in proteins (e.g. immunoglobulin-like domains in many

transmembrane proteins) are due to duplications of certain exons.

Occasionally, however, duplications may also be the cause of genetic disorders. The most frequent mechanism of duplication is homologous unequal crossover as described for large deletions. In fact, most large duplications generated as the reciprocal product of a deletion resulting from homologous unequal crossover. Duplications are less common, however, than their theoretically reciprocal deletions (e.g. see Ref. (245), for the *DMD* gene). This may be due to the nonpathogenicity of a duplication (e.g.  $\alpha$ -globin genes; (173)), elimination of duplications as is the case for the *HPRT1* gene, or to the fact that not all mechanisms that lead to deletions also produce duplications. A large and common duplication has been identified in cases of Charcot-Marie-Tooth disease type 1A (246). This duplication involves 1.5 Mb of DNA on chromosome 17p containing the peripheral myelin protein 22 (*PMP22*) gene. It results from homologous unequal crossover events between 24 kb repeats that flank the duplicated region. The reciprocal deletion product of this recombination event is responsible for a completely different clinical phenotype: HNPP (Figure 7-8). Another notable duplication of at least 500 kb that includes the *PLP1* gene is a frequent cause of Pelizaeus-Merzbacher disease (247). The pathogenetic mechanism of these duplications involves unequal crossing-over in meiosis mediated by “duplicons” in the genome (187).

The molecular defect in the majority of cases with ectrodactyly type SHFM3 on chromosome 10q24, is an approximately 0.5 Mb tandem duplication. The precise pathogenetic mechanism of this duplication is unknown (248). Additional gene duplications causing recognizable syndromes include the *APP* duplication

causing early-onset Alzheimer disease (249), the *SNCA* duplication and Parkinson disease (250) and the triplication of ~605 kb segment containing the *PRSS1* gene in families with hereditary pancreatitis (251).

### 7.3.12 Copy Number Variation in Association with Disease

CNVs are a form of genomic diversity that involves DNA sequences  $\geq 1$  kb in length that are present in the human genome in a variable number of copies. CNVs may be recurrent (which arise by NAHR) or nonrecurrent (which arise by nonhomologous end joining and recombination-based mechanisms) (252, 252a). Such gross duplications/deletions are not only rather abundant but also often occur at polymorphic frequencies. Conrad et al. (53) generated a comprehensive map of >8500 validated CNVs >500 bp (detected in 41 Europeans/West Africans) that together cover a total of 112.7 Mb (3.7% of the genome). These authors estimated that 39% of the validated CNVs overlapped 13% of RefSeq genes (NCBI mRNA reference sequence collection). Further, they concluded that the CNVs detected resulted in the “unambiguous loss of function” of alleles for 267 different genes.

It has been estimated that on average, 73–87 genes vary in terms of their copy number between any two individuals (253). This high degree of interindividual variability with regard to gene copy number has challenged traditional definitions of wild type and “normality” and even the very concept of a “reference genome” itself. High-resolution breakpoint mapping is a prerequisite for the accurate assessment of CNV size, the identification of the genes and regulatory elements affected, and hence, for the determination of the consequences of CNV for gene expression (254) and the phenotypic sequelae (190,255–257). This notwithstanding, it is already becoming clear that these consequences may go far beyond the physical bounds of a given CNV. For example, a CNV involving the human *HBA* gene has a dramatic influence on the expression of the *NME4* gene some 300 kb distant (258). In addition, a 5.5 kb microduplication of a conserved noncoding sequence with demonstrated enhancer function, about 110 kb downstream of the bone morphogenic protein 2 (*BMP2*) gene, has been found to cause brachydactyly type 2A in two families (259).

It may well be that the precise extent and/or location of many CNVs will vary between individuals, thereby further increasing both the mutational and phenotypic heterogeneity. The extent to which CNVs are likely to contribute to the diversity of human phenotypes, including “single gene defects,” genomic disorders, and complex disease, is increasingly being recognized. Thus, CNV of the *FCGR3B* genes is a determinant of susceptibility to immunologically mediated glomerulonephritis (260). CNVs in the *CCL3L1* and *DEFB4* genes have also been found to be associated with increased

susceptibility to HIV infection and Crohn’s disease, respectively (261,262), whereas rare CNVs associated with various complex phenotypes have been identified in studies of schizophrenia (263), epilepsy (264), and severe early-onset obesity (265). CNVs are now being widely recruited to genome-wide association studies (GWAS) with the aim of assessing their influence on human disease causation/susceptibility (256,266,267).

To date, several dozen human disease conditions have been identified, which are either caused by CNVs or whose relative risk is increased by CNVs (256,268). Remarkably, an excess of both rare and de novo CNVs has been identified in patients with psychiatric disorders and obesity (263,265,269–273). These findings point to genetic heterogeneity in these conditions thereby illustrating the likely complexity inherent in identifying all disease-causing CNVs. Intriguingly, Shlien et al. (274) have reported a highly significant increase in CNV number among patients with Li–Fraumeni syndrome, carriers of inherited *TP53* mutations. Hence, it would appear that heritable genetic variants have the potential to modulate the rate of germline CNV formation.

It is already clear that the disease relevance of CNVs represents a continuum, stretching from “neutral” polymorphisms on the one hand to directly pathogenic copy number changes on the other (256). Between these two extremes may lie those CNVs that are capable of acting as predisposing (or protective) factors in relation to complex disease (275,276). Thus, for example, a 117 kb deletion encompassing the *UGT2B17* gene has been found to be associated with an increased risk of osteoporosis (277). Intriguingly, some germline CNVs appear to predispose to disease even although no known genes reside within their boundaries (278,279). Importantly, a 520 kb micro-deletion has been identified at 16p12.1, which predisposes to various neuropsychiatric phenotypes as a single copy number mutation and aggravates neurodevelopmental disorders if it co-occurs together with other large deletions and duplications (276). It remains to be seen whether “CNV equivalents,” <1 kb in size, that actually occur rather more frequently than true CNVs (>1 kb) (53), will also be relevant to disease. What is already clear is that, over the coming years, an increasing number of important CNV-disease associations are going to come to light (257).

### 7.3.13 Gene Conversion

Gene conversion is the modification of one of two alleles by the other. It involves the nonreciprocal correction of an “acceptor” gene or DNA sequence by a “donor” sequence, which itself remains physically unchanged. In most known instances of gene conversion as a cause of human genetic disease, the functional gene has been wholly or partially converted to the sequence of a highly homologous and closely linked pseudogene, which therefore acts as the donor sequence (280). Probable examples include

the genes for steroid 21-hydroxylase (*CYP21*; (281)), polycystic kidney disease (*PKD1*; (282)), neutrophil cytosolic factor p47-*phox* (*NCF1*; (283)), immunoglobulin  $\lambda$ -like polypeptide 1 (*IGLL1*; (284)), glucocerebrosidase (*GBA*; (285)), von Willebrand factor (*VWF*; (286)), and phosphomannomutase (*PMM2*; (287)). These gene/pseudogene pairs are all closely linked with the exception of the *VWF* gene (12p13) and its pseudogene (22q11-q13), and the *PMM2* gene (16p13) and its pseudogene (18p). Together, these two exceptions would seem to establish a precedent for the occasional occurrence of gene conversion between unlinked loci in the human genome.

An *in silico* analysis of the DNA sequence tracts involved in 27 well-characterized nonoverlapping gene conversion events in 19 different genes reported in the context of inherited disease was recently performed (288). It was noted that gene conversion events tended to occur within (C+G)- and CpG-rich regions and that sequences with the potential to form non-B DNA structures (and which might be involved in the generation of double-strand breaks that could, in turn, serve to promote gene conversion) occurred disproportionately within maximal converted tracts and/or short flanking regions. Maximal converted tracts were also found to be enriched in a truncated version of the chi-element (a TGGTGG motif), immunoglobulin heavy chain class switch repeats, translin target sites, and several novel motifs including (or overlapping) the classical meiotic recombination hotspot, CCTCCCCCT (288). Finally, it was found that gene conversions tended to occur in genomic regions that had the potential to fold into stable hairpin conformations. Taken together, these findings support the concept that recombination-inducing motifs, in association with alternative (non-B DNA) conformations, can promote recombination in the human genome.

The large number of duplicated gene sequences in the human genome implies that a considerable number of disease-associated mutations could originate via interlocus gene conversion. A genome-wide computational approach to identify disease-associated mutations derived from interlocus gene conversion events recently revealed hundreds of known pathological mutations that could have been caused by interlocus gene conversion (289). In addition, several dozen high-confidence cases of inherited disease mutations resulting from interlocus gene conversion were identified in about 1% of all genes analyzed. About half of the donor sequences associated with such mutations were functional paralogous genes, suggesting that epistatic interactions or differential expression patterns would determine the impact upon fitness of a single amino acid substitution between duplicated genes. In addition, Casola et al. (289) identified thousands of hitherto undescribed deleterious mutations that could potentially arise via interlocus gene conversion. It would therefore appear as if the impact of interlocus gene conversion upon the spectrum of human inherited disease may be considerably greater than has hitherto been appreciated.

Although mutations that are detrimental to the fitness of individuals are expected to be rapidly purged from the population by natural selection, some pathological mutations are nevertheless retained at high frequencies in human populations. Several hypotheses have been proposed to account for this apparent paradox (high new mutation rate, genetic drift, overdominance, or recent changes in selective pressure). However, there is an additional process that appears to contribute to the spreading of deleterious mutations: GC-biased gene conversion (gBGC), a process associated with recombination that tends to favor the transmission of GC-alleles over AT-alleles. Necsulea et al. (290) have shown that the spectrum of amino acid-altering polymorphisms in human populations exhibits the footprints of gBGC. This pattern is not explicable in terms of selection and is evident with all nonsynonymous mutations, including those predicted to be detrimental to protein structure and function as well as those that have been implicated in the causation of human genetic disease. These results indicate that gBGC meiotic drive contributes to the spreading of deleterious mutations in human populations.

### 7.3.14 Insertion–Deletions (Indels)

A relatively rare type of mutation causing human genetic disease is the *indel*, a complex lesion that appears to represent a combination of micro-deletion and micro-insertion. One example is provided by the 9 deleted base pairs encoding codons 39–41 of the  $\alpha$ 2-globin (*HBA2*) gene that were replaced by 8 inserted bases that served to duplicate the adjacent downstream sequence (DSS) (291). Indels constitute a fairly infrequent type of lesion causing human genetic disease; some 1.5% of lesions in HGMD fall into this category.

Several indel hotspots have been noted in a meta-analysis of HGMD data on 211 different indels underlying genetic disease (292). A GTAAGT motif was found to be significantly overrepresented in the vicinity of the indels studied. The change in complexity consequent to a mutation was also found to be indicative of the type of repeat sequence involved in mediating the event, thereby providing clues as to the underlying mutational mechanism. The majority of indels (>90%) were explicable in terms of a two-step process involving established mutational mechanisms. Indels equivalent to double base-pair substitutions (22% of the total) were found to be mechanistically indistinguishable from the remainder and may therefore be regarded as a special type of indel.

### 7.3.15 Other Types of Complex Rearrangement

Complex mutational events that involve combined gross duplications, deletions, and/or insertions of DNA sequence have been not infrequently observed and

together constitute ~1% of entries in HGMD. One example of this type of gene defect is a 10.9kb deletion coupled with a 95 bp inversion in the factor IX (*F9*) gene causing hemophilia B (293). The molecular characterization of this type of lesion is often extremely complicated, and in most cases, the underlying mutational mechanisms could not be readily inferred.

Recently, however, a meta-analysis of 21 complex gene rearrangements derived from the HGMD revealed that all but one could be accounted for by a model of SRS, involving twin or multiple rounds of replication slippage (151). Thus, of the 20 complex gene rearrangements, 19 (7 simple double deletions, 1 triple deletion, 2 double mutational events comprising a simple deletion and a simple insertion, 6 simple indels that may constitute a novel and noncanonical class of gene conversion, and 3 complex indels) were compatible with the model of SRS in *cis*; by contrast, the remaining indel in the *MECP2* gene appears to have arisen via interchromosomal replication slippage in *trans*.

A novel type of complex genomic rearrangement, comprising intermixed duplications and triplications of genomic segments, has recently been described at both the *MECP2* and *PLP1* loci (294). These complex rearrangements share a common genomic organization viz., a duplication-inverted triplication-duplication (DUP-TRP/INV-DUP), in which the triplicated segment is inverted and located between directly oriented duplicated genomic segments. The DUP-TRP/INV-DUP structures appear to be mediated by inverted repeats, up to >300 kb apart.

### 7.3.16 Multiple Simultaneous Mutations

Transient hypermutability is a general mutational mechanism with the potential to generate multiple synchronous mutations, a phenomenon probably best exemplified by “closely spaced multiple mutations” (CSMMs). From a collection of human inherited disease-causing multiple mutations, Chen et al. (295) retrospectively identified numerous potential examples of pathogenic CSMMs that exhibited marked similarities to the CSMMs reported in other systems. These examples included (i) eight multiple mutations, each comprising three or more components within a sequence tract of <100 bp (*CBS*, *MPZ*, *OPN1LW*, and *STK1* genes), (ii) three possible instances of “mutation showers” in the *PTCH1*, *FANCA*, and *KNG1* genes, respectively, and (iii) numerous highly informative “homocoordinate” mutations (multiple mutations involving the same mutation type).

Recently, a remarkable phenomenon has been reported in multiple cancer samples: The presence of tens to hundreds of genomic rearrangements involving spatially localized genomic regions (296). These complex rearrangements primarily affected a single chromosome, although in some cases, multiple apparently concomitant alterations affected several different chromosomes. Stephens et al. convincingly argued that

these massive, yet spatially localized, genomic rearrangements must have resulted from a single catastrophic event (which they termed “chromothripsis”) rather than from a series of progressive and hence independent alterations. Chromothripsis also appears to be capable of explaining the generation of some complex de novo structural rearrangements in the germline (297). An illustrative example pertains to a highly complex chromosomal rearrangement, identified in a child with severe congenital abnormalities, which comprised at least 12 de novo breakpoint junctions and involved chromosomes 1, 4, and 10. These breakpoints were clustered in small genomic regions of up to 3.5 Mb in size on each chromosome. Reconstruction of the derivative chromosomes indicated that the breakpoints formed concordantly oriented pairs on the reference genome. Both intra- and interchromosomal junction sequence features were compatible with those commonly associated with NHEJ (297). The insights generated from the seminal work of Stephens and his colleagues may well help us to understand the mutational mechanisms underlying some previously reported germline complex rearrangements (298). For example, with respect to the de novo mutational event on chromosome 2 in a patient with Waardenburg syndrome and other congenital defects, the original authors suggested that all five breaks might have occurred simultaneously but were unable to explain why the breakpoints had occurred within a single chromosome (299). In the light of our emerging knowledge of chromothripsis, the idea that this complex rearrangement could have been generated in such a way as to be compatible with the NHEJ repair of simultaneously generated DSBs becomes quite attractive. Liu and colleagues subsequently investigated 17 subjects with various development abnormalities by means of high-resolution genome analysis (300). Constitutional multiple copy number changes, including deletions, duplications, and/or triplications, as well as inversions were observed in all cases. Strikingly, in each case, all rearrangements occurred within a single chromosome; in 15 of the 17 cases, the rearrangements were localized to the distal half of the affected chromosomal arms. FISH and breakpoint junction data indicated that all additional copies of the duplicated and triplicated segments appear to be randomly joined, forming a large “breakpoint junction cluster” on 9q21. By analogy with the phenomenon of chromothripsis, the observation of these extremely complex rearrangements in a single chromosome was also described as a chromosome catastrophe event (300). However, this kind of chromosomal change cannot be easily explained by the previously described NHEJ repair of simultaneously generated DSBs. Instead, Liu and colleagues envisaged the involvement of a replicative mechanism in the generation of this complex chromosome catastrophe event comprising multiple duplications and/or triplications; they regarded MMBIR as the most likely underlying mechanism. They further suggested that a

potential replication fork collapse at 9q21 could account for the breakpoint clustering therein (300).

### 7.3.17 Molecular Misreading

Long runs of adenines (and perhaps other mononucleotides or dinucleotides) promote a phenomenon termed “molecular misreading” by which DNA replication/RNA transcription and/or translation result in erroneous products with different numbers of (A)s derived from the original DNA sequence (301). In a family with hypobetalipoproteinemia, a deletion of one C in the A<sub>5</sub>CA<sub>3</sub> coding sequence of the *APOB* gene results in a run of (A)<sub>8</sub>. The patient, however, did not have severe disease, because some ApoB protein was made. This was the result of molecular misreading in which ~10% of the resulting mRNAs contained (A)<sub>9</sub> instead of the expected (A)<sub>8</sub>; this partially restored the reading frame thereby templating the synthesis of low amounts of normal ApoB (302). Similarly, a family with mild to moderately severe hemophilia A with a deletion of one T within the coding A<sub>8</sub>TA<sub>2</sub> sequence of the *F8* gene has been reported. The partial “correction” of the phenotype was due to restoration of the reading frame because of molecular misreading in which ~5% of the resulting RNAs contained (A)<sub>11</sub> instead of the expected (A)<sub>10</sub>. In this family, there was also evidence for ribosomal frameshifting during translation of the mutant RNA (303).

Another example of this phenomenon was observed in the *APC* gene. A T-to-A transversion is present in the coding A<sub>3</sub>TA<sub>4</sub> sequence of the *APC* gene in 6% of Ashkenazi Jews, and in about 28% of Ashkenazim with a family history of colorectal cancer. This mutation creates a small hypermutable region, indirectly causing cancer predisposition because there are many somatic cells in which stretches of (A)<sub>9</sub> occur instead of the expected (A)<sub>8</sub>; the (A)<sub>9</sub> results in frameshifting and a truncated dysfunctional APC (304). Interestingly, in the neurofibrillary tangles, neuritic plaques, and neuropil threads in the cerebral cortex of Alzheimer disease and Down syndrome, abnormal forms of  $\beta$ -amyloid precursor protein and ubiquitin B have been observed. These aberrant proteins were produced because of +1 frameshifting that resulted from a deletion of AG in a sequence GAGAG that occurred in the coding regions of both genes (*APP* and *UBB*, respectively). This dinucleotide deletion was again the result of molecular misreading during transcription or posttranscriptional editing of RNA (305). This mechanism is likely to yield a considerable quantity of abnormal RNA molecules and protein products in somatic cells (306).

### 7.3.18 Germline Epimutations

*Epimutations* are modifications of DNA that constitute clonally heritable (yet potentially reversible) alterations in the transcriptional status of a gene that lead to the

abnormal silencing of that gene. Epimutations are not mutations *sensu stricto* since they do not alter the gene’s nucleotide sequence. However, germline epimutations of the *MLH1* gene have been reported in individuals with multiple cancers (307) and in the *MLH1* and *MSH2* genes in hereditary nonpolyposis colorectal cancer (308). These heritable inactivating epimutations are characterized by mono-allelic hypermethylation of the *MLH1* or *MSH2* genes and, to all intents and purposes, are functionally equivalent to conventional mutations. A maternal epimutation in the *GNAS* gene has also been reported as a cause of Albright osteodystrophy and parathyroid hormone resistance (309). With the determination of the human methylome (80) and the recent recognition that DNA sequence polymorphisms can exert an effect on gene function via allele-specific methylation in *cis* (310), the number of recognized epimutations should rise quite significantly in the coming years. If eventually shown to be both of pathological significance and heritable, some examples of histone modification (311,312) or RNA editing (313,314) could also turn out to represent “honorary mutations.”

### 7.3.19 Frequency of Disease-Producing Mutations

*Mutation frequency within genes:* The frequency of different molecular defects is not the same for every gene and every disorder. Indeed, human disease genes exhibit very considerable allelic heterogeneity in terms of their mutational spectra; for some genes, a few predominant disease alleles predominate whereas for others, there is a wide range of disease alleles, each relatively rare (315). The mutational spectrum depends very largely on the DNA sequence characteristics of the gene in question (e.g. the presence of repeat units or homologous sequences), and the function of, and evolutionary constraints experienced by, its encoded protein (316). For some genes, deletions predominate; for others, one particular type of lesion such as an inversion may be especially common. Some genes exhibit mainly frameshifts and stop codons associated with a specific disorder, whereas others manifest mainly missense mutations for a given phenotype, or expansions of trinucleotide repeats.

Disease mutations are nonuniformly distributed within genes (317). Such mutations were found to be statistically overrepresented in conserved domains, and underrepresented in variable regions, even after allowing for the amino acid site variability of domains over long-term evolutionary history. This finding suggests that there is a nonadditive influence of amino acid site conservation on the observed intragenic distribution of disease mutations.

*Mutation frequency within human populations:* Population genetic considerations are also likely to be very important in determining why some mutations occur frequently, either within a patient cohort or in

the population at large (see Frequency of Inherited Disorders Database, <http://archive.uwcm.ac.uk/uwcm/mg/fidd/>; FINDbase, <http://www.findbase.org/>). Selection, migration, and genetic drift are all likely to play a role as well as the mutation rate (318–320). Thus, the mutational spectrum of the *PAH* gene underlying phenylketonuria appears to result from a range of different factors including founder effect, range expansion and migration, genetic drift, and possibly also heterozygote advantage (321). Selection can also serve to maintain deleterious mutations at high frequencies in particular populations by overdominant selection (heterozygote advantage). Good examples of this phenomenon are provided by a reduction in risk of severe malaria associated with female heterozygotes and male hemizygotes for mutations in the X-linked *G6PD* gene (322,323), for individuals heterozygous for the  $\beta$ -globin (*HBB*) sickle cell mutation, Glu6Val (324), and for individuals heterozygous and homozygous for  $\alpha^+$ -thalassemia (325). Intriguingly, however, the protection against malaria afforded by sickle cell disease and  $\alpha^+$ -thalassemia when inherited individually is lost when the two conditions are co-inherited (326). Other possible examples of heterozygote advantage include an elevated cortisol response in heterozygous carriers of *CYP21A* mutations (327), higher values for hemoglobin, serum iron and transferrin saturation in women heterozygous for *HFE* gene mutations (328), resistance to prion infection conferred by a common prion protein (*PRNP*) polymorphism (329), resistance to severe sepsis in heterozygous carriers of the factor V Leiden polymorphism, Arg506Gln (330), and increased keratinocyte cell survival in individuals heterozygous for *GJB2* gene mutations (331). Resistance to cholera toxin (332), protection against bronchial asthma (333), and resistance to *Pseudomonas aeruginosa* infection (334) have all been mooted as possible bases for overdominant selection in heterozygous carriers of *CFTR* gene mutations. However, cystic fibrosis heterozygotes have been shown to secrete chloride at the same rate as individuals lacking *CFTR* gene mutations (335).

A number of genetic diseases are known to be particularly prevalent in Jewish populations (336,337). The presence of four distinct lysosomal storage diseases at significant frequencies among Ashkenazi Jews has often been considered as providing evidence for a selective advantage accruing to heterozygotes in this population. However, evidence in support of the idea of genetic drift appears to be more compelling (338,339).

Selection may also act at an extremely early stage to boost the frequency of some mutations that are deleterious at a later stage in development. For example, gain-of-function missense mutations in the fibroblast growth factor receptor 2 (*FGFR2*) gene responsible for Apert syndrome have been shown to confer a selective advantage on spermatogonial cells by promoting the clonal expansion of mutant cells (340,341).

### 7.3.20 Functional Characteristics of Human Disease Genes

Human disease genes appear to be distinguishable from “nondisease genes” (in reality, the latter can only be defined as genes that are not yet known to cause inherited disease) in terms of a range of features including gene structure, gene expression, physicochemical properties, protein structure, and evolutionary conservation (31,316,342–347). Thus, human disease genes are characterized by the greater length of their encoded amino acid sequences, a larger numbers of longer introns, a broader range of tissue expression, and a wider phylogenetic distribution (343,348). Human disease genes are also known to be unevenly distributed between the human chromosomes (349,350). Further, synonymous nucleotide substitutions appear to occur at a higher rate in human disease genes, a finding that may reflect increased mutation rates in the chromosomal regions in which disease genes are found (349). It may be that disease genes are more prevalent in genomic regions that experience elevated rates of mutation (351). Another possible explanation is that the disease gene set may contain a disproportionately lower number of genes expressed in the germline (349). This is because mutations in such genes might be expected to be more effectively repaired by transcription-coupled repair (transcription-coupled repair in the germline appears to account for the strand asymmetry that the human genome exhibits in terms of inherited mutations; (352,353)). Strand asymmetries with respect to the mutation rate may, however, also arise through the influence of DNA replication origins (354), recombination (355,356), and strand-biased repair (357).

### 7.3.21 Mutation Nomenclature

Some consistency in the way in which mutations are described is essential for the accurate and unambiguous reporting and curation of mutation data. Most guidelines on how to describe mutational changes in human genes are to be found in (358) and on the Human Genome Variation Society (HGVS) website (<http://www.hgvs.org/mutnomen/>). A program, *Mutalyzer*, is available to check sequence variation nomenclature (<http://www.lovd.nl/mutalyzer>) using a human genome reference sequence and following the current recommendations of the HGVS; *Mutalyzer* is capable of handling most types of mutations including nucleotide substitutions, deletions, duplications, insertions, indels, and splice-site changes (359).

### 7.3.22 Mutations in Gene Evolution

Mutations in human gene pathology and evolution represent two sides of the same coin in that those same mutational mechanisms that have frequently been implicated in

human pathology have also been involved in potentiating evolutionary change (47). Regardless of whether they are advantageous, disadvantageous, or neutral, these mutational changes and their putative underlying causal mechanisms are very similar. It is now clear that the gene has often been a dynamic entity over evolutionary time, not a static one. Indeed, during vertebrate evolution, many genes have undergone gross rearrangement as a result of the action of a variety of mutational processes including insertion, inversion, duplication, repeat expansion, translocation, or deletion. What links pathology and evolution is the underlying genomic architecture with its hitherto largely unexplored vocabulary of structural elements, and different types and patterns of repetitive DNA sequences (189). It can thus be seen that the mutational spectra of germline mutations responsible for inherited disease, somatic mutations underlying tumorigenesis, polymorphisms (either neutral or functionally significant), and differences between orthologous gene sequences, exhibit remarkable similarities implying that they are very likely to have causal mechanisms in common.

## 7.4 CONSEQUENCES OF MUTATIONS

### 7.4.1 Mutations Affecting the Amino Acid Sequence of the Predicted Protein, but Not Gene Expression

Many missense mutations (i.e. nucleotide substitutions that result in an amino acid substitution) cause hereditary disease in humans. Missense mutations are of importance in understanding the structure or function of a protein since they usually occur in amino acid residues of structural or functional significance (10). Occasionally, however, not only is the mutated residue not conserved in mouse, but also the substituting residue in humans is identical to its wild-type counterpart in the orthologous (e.g. murine) gene (360). It is thought that the most likely explanation for the majority of these cases of fixation of disease mutations in mice is *compensatory mutation*. The chimpanzee genome has been found to harbor a number of examples of potentially compensated mutations (PCMs), defined as human disease-causing or disease-associated missense mutations for which the substituting amino acid is identical to the wild-type amino acid residue at the orthologous position in chimpanzee (361). The absence of strongly deleterious consequences of a specific PCM in chimpanzee would be explicable either by virtue of the very different (simian) environment or by dint of hitherto unidentified variants (“compensatory mutations”) in the chimpanzee genome that have served to epistatically buffer the PCM (361). It should be noted, however, that the PCM may only have become seriously disadvantageous in the human lineage, either as a consequence of other lineage-specific genetic changes or due to changes in the human environment and/or lifestyle (362,363). In this case, it would not have been

necessary for the chimpanzee PCM to be compensated for at any time, which is why the qualifier “potentially” is important when PCMs are defined on the basis of current genetic and clinical data.

It is sometimes difficult to establish a causative link between a missense mutation and a disease phenotype (364). The absence of the mutation in a large sample (usually 200 individuals) from the same ethnic group as the patient serves to exclude the possibility of a common polymorphism. Amino acid substitutions in evolutionarily conserved residues can also be good candidates for true pathogenicity (10). If the function of the protein is known, assessment of the effect of the missense mutation can be performed by *in vitro* mutagenesis and functional assay. Finally, the introduction of the mutation into an entire organism (e.g. transgenic mice) and the study of its systemic effects provide one of the best means to assess its contribution to a particular clinical phenotype. Amino acid substitutions can be shown to reduce or abolish the physiological function of a protein; for example, missense mutations have been identified in factor VIII that abolish thrombin cleavage, which is necessary for its activation (365), interfere with binding to other proteins such as vWF (366), or create or abolish N-glycosylation sites (367). In other proteins, mutations have been identified, for example in DNA binding domains, catalytic domains, transmembrane domains, ATP-binding regions, receptor-ligand contact sites, phosphorylation, or other chemical modification sites. Missense mutations may also affect protein folding causing a dramatic change in secondary and tertiary structures such that the protein can no longer fulfill its physiological function.

A classical example of a missense mutation in the active site of an enzyme is provided by  $\alpha$ 1-antitrypsin, Pittsburgh, found in an individual with a fatal bleeding disorder (368). The underlying mutation in the  $\alpha$ 1-antitrypsin (*SERPINA1*) gene substituted Arg for Met358 within the active site of the molecule. Substitution by Arg served to alter the substrate specificity of  $\alpha$ 1-antitrypsin by converting its “bait loop” (which is specific for elastase) to one that was specific for thrombin. In effect, the molecule lost its anti-elastase activity and became a serine protease inhibitor capable of inhibiting thrombin and factor Xa.

Mutations involving gains of glycosylation have generally been considered rare, and the pathogenic role of the new carbohydrate chains has never been formally established (369); however, the three children identified with Mendelian susceptibility to mycobacterial disease were homozygous with respect to a missense mutation in the *IFNGR2* gene that created a new N-glycosylation site in the IFN $\gamma$ R2 chain. The resulting additional carbohydrate moiety was found to be both necessary and sufficient to abolish the cellular response to IFN $\gamma$ . From 10,047 HGMD mutations in 577 genes encoding proteins trafficked through the secretory pathway, 142 candidate missense

mutations (~1.4%) in 77 genes (~13.3%) for potential gain of *N*-glycosylation were identified. Six mutant proteins were shown to bear new *N*-linked carbohydrate moieties. Thus, it may be that an unexpectedly high proportion of mutations causing human genetic disease do so via the creation of new *N*-glycosylation sites. Indeed, the pathogenic effects of these mutations may be a direct consequence of the addition of *N*-linked carbohydrate.

Missense mutations can result in disease by (1) elimination or reduction of the physiological activity/role of the protein; (2) gain-of function by which the amino acid substitution creates new functional capabilities of the protein in biochemical and developmental processes in which the protein either does not participate or has a different role; (3) change of the target function of another protein as in the case of the mutation in the protein C cleavage site at Arg 506 of coagulation factor V, which is associated with thrombophilia (370), or in the case of a mutation in the thrombin cleavage site of factor VIII that eliminates normal activation of factor VIII (365), or in the case of severe obesity from childhood and R236G in the human pro-opiomelanocortin (*POMC*) gene that disrupts the dibasic cleavage site between beta-melanocyte-stimulating hormone (beta-MSH) and beta-endorphin (371); and (4) participation of the mutant polypeptide in protein complexes, which renders the entire complex abnormal or nonfunctional, as in the case of the triple helical structure of certain collagens in which incorporation of one abnormal collagen chain results in “protein suicide” or an abnormal structure that degrades rapidly (372).

Missense mutations have a multitude of different effects on protein structure and function including (i) introduction of larger residues within the hydrophobic protein core leading to adverse interactions between residues (373,374), (ii) introduction of buried charged residues (373–375), (iii) disruption of protein–protein interactions (376), (iv) disruption of hydrogen bonding (373,375), (v) interference with DNA binding (373), (vi) breakage of disulfide covalent linkages (373), (vii) mutation of catalytic residues (375,377), (viii) perturbation of metal binding (373), (ix) loss of post-translational modification sites (378), (x) gain of intrinsic disorder (374,379), (xi) loss of stability (380,381), and (xii) disruption of quaternary structure (373,382).

Without in-depth analytical studies, missense mutations are often difficult to distinguish from polymorphisms with little or no clinical significance, either in the context of candidate gene sequencing studies (383) or in the context of exome sequencing studies (384). In the “post-genome era,” a substantial amount of human genetic variation will become amenable to high-throughput analysis in the form of SNPs, and many of these SNPs will influence directly the structure, function, or expression of genes and the RNAs/proteins they encode. Prior knowledge as to which SNPs are most likely to be clinically relevant would greatly enhance the power of studies

that aim to identify disease genes through the genotypic screening of patients in both families and populations. Inclusion of structural/functional information could be especially important in the elucidation of multifactorial disease, where genetic heterogeneity and complex interactions between genes and environment have so far limited the success of genetic epidemiological studies (385). Recently, several predictive models have been developed which employ a number of different biophysical parameters to estimate the likely functional impact of an amino acid substitution on the structure and function of a protein (7,380,386,387). These models have been used to distinguish reasonably and successfully between pathological substitutions, functional polymorphisms, and neutral polymorphisms. Vitkup et al. (388) have claimed that mutations at arginine and glycine residues are together responsible for about 30% of cases of genetic disease, whereas random mutations at tryptophan and cysteine have the highest probability of causing disease.

## 7.4.2 Mutations Affecting Gene Expression

Mutations that do not result in amino acid substitution invariably affect gene expression, that is, transcription, RNA processing, and maturation, translation, or protein stability. Total or partial gene deletions, insertions, inversions, and other gross rearrangements obviously result in the loss of gene expression. These types of mutations are usually less frequent unless the genomic sequence environment of specific genes (e.g. presence of repeats) predisposes to such lesions. Disorders with high frequencies of gross rearrangements include  $\alpha$ -thalassemia, DMD, steroid sulfatase deficiency, and hemophilia A. Some partial gene deletions that eliminate one or a few exons in-frame result in milder clinical phenotypes because gene expression is not totally eliminated; the resulting protein may lack an amino acid domain that is not critical for its function (389).

## 7.4.3 Promoter (Transcription Regulatory) Mutations

Microlesions within proximal gene regulatory regions currently comprise only ~1.7% of known mutations causing or associated with human inherited disease (see HGMD). Their relative rarity may be in part because not all regulatory elements occur immediately 5′ to the genes that they regulate. Indeed, many such elements are located within the first exon, within introns (390) or within 5′ or 3′ UTRs. In the same vein, upstream ORFs (uORFs), present in 50% of human genes, often impact on the expression of the primary ORFs; indeed, both mutations and polymorphisms have been reported within uORFs that can modulate or even abolish the expression of the downstream gene (391,392).

Mutations in known promoter motifs usually lead to reduced (or occasionally increased) mRNA levels. Such

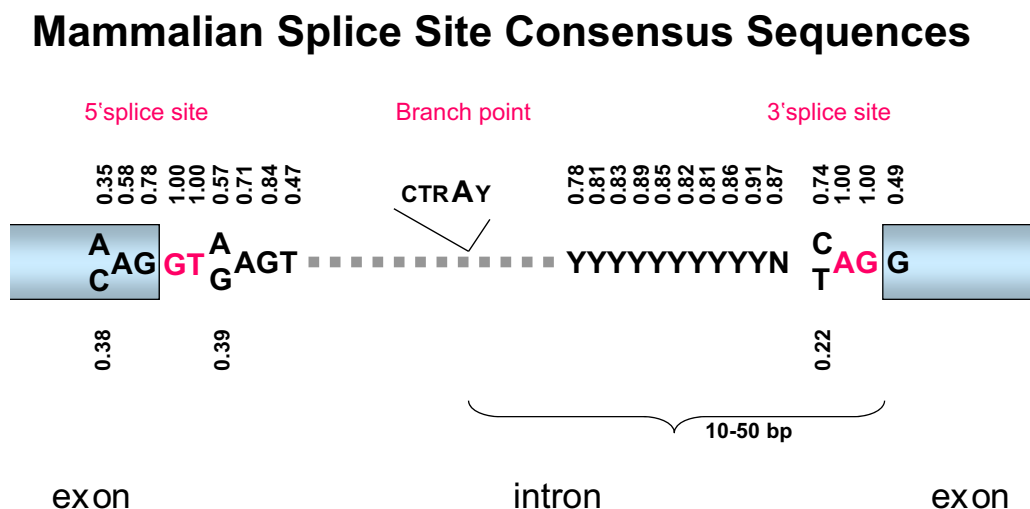

mutations have been studied in the TATA box of the  $\beta$ -globin (*HBB*) gene (393). Other disease-associated nucleotide substitutions occurring within DNA motifs that bind transcription factors include those located in the CACCC motif of the  $\beta$ -globin (*HBB*) gene influencing transcription factor EKLf binding (394,395), several motifs in the  $\gamma$ -globin (*HBB*) genes (396), the CCAAT motif of the *F9* gene influencing C/EBP binding (397), the SP1 motif of the *LDLR* gene promoter (398), the HNF-1 binding site in the *PROC* gene (399), and the binding site for the transcription factor Oct-1 in the lipoprotein lipase (*LPL*) gene (400). These few examples are only representatives of a total of over 2200 known promoter mutations listed in HGMD and causing human genetic disease. The importance of these mutants lies in the specific DNA sequences thereby implicated in binding to transcription factors. Although most of the known mutations reduce the levels of mRNA production, some substitutions actually increase it. Examples include various lesions in the promoters of the  $\gamma$  and  $\text{A}\gamma$  globin (*HBB1* and *HBB2*) genes that cause hereditary persistence of fetal hemoglobin (HPFH) due to the inappropriate continuation of  $\delta$ -globin (*HBB*) gene expression into adult life (401) and a gain-of-function (creates a GATA1 binding site) regulatory SNP, which is located in a non-genic region between the  $\alpha$ -globin genes and their upstream regulatory elements (402). An increase in the distance of promoter elements from the transcriptional start site may also result in gene silencing. Such an example has been found in the promoter elements of the *CSTB* gene in EPM1 (126). Mutations that alter the transcriptional regulation of gene expression have been reviewed in (403).

The concomitant change in local DNA sequence complexity surrounding a substituted nucleotide is directly related to the likelihood of a regulatory mutation coming

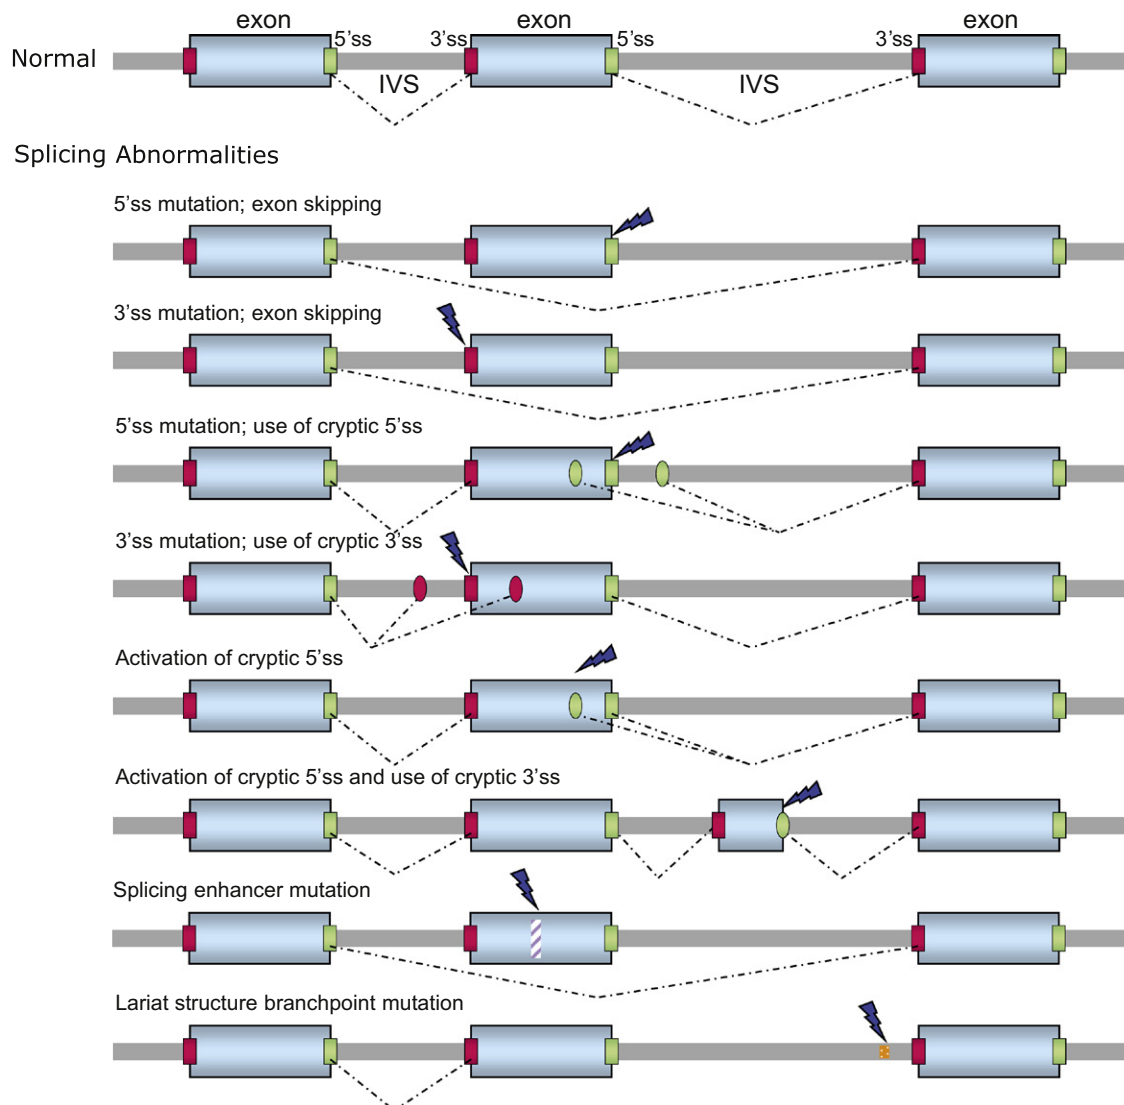

to clinical attention (67). This finding is consistent with the view that DNA sequence complexity is a critical determinant of gene regulatory function and may reflect the internal axial symmetry that frequently characterizes transcription factor binding sites. Polymorphisms in the promoter region that are associated with differential levels of gene expression may predispose to common disorders. For example, a G>A SNP, at nucleotide -6 relative to the transcriptional initiation site of the angiotensin (*AGT*) gene, influences the basal level of transcription and may predispose to essential hypertension (404). In excess of 400 disease-associated promoter polymorphisms are listed in HGMD plus >700 functional promoter polymorphisms that significantly increase or decrease promoter activity but which have not yet been associated with a clinical phenotype.

#### 7.4.4 mRNA Splicing Mutants

Single base-pair substitutions in splice junctions constitute at least 10% of all mutations causing human inherited disease. There are, however, a wide variety of mutations within both introns and exons that can affect normal RNA splicing (see Ref. (405) for review). The different mechanisms by which disruption of pre-mRNA splicing play a role in human disease have been reviewed in Ref. (406). The most commonly found mutations occur in the invariant dinucleotides GT and AG found at the beginning and end of the donor (5') and acceptor (3') consensus splice sequences (see Figure 7-11 for the consensus splice elements and Figure 7-12 for the different kinds of RNA splicing abnormalities). Almost all of these mutations cause either exon skipping or cryptic splice-site utilization resulting in the severe reduction or absence of normally spliced mRNA. In addition, mutations in nucleotides +3, +4, +5, +6, -1, and -2 of

**FIGURE 7-11** Consensus sequences for the donor (5' splice) and acceptor (3' splice) sites and the branchpoint. Numbers above or below the nucleotides correspond to frequencies of a given nucleotide in a large number of mammalian splice-site sequences. Note that the dinucleotides GT and AG (in red) at the beginning and end of the intron are invariant.

**FIGURE 7-12** Examples of splicing abnormalities in introns of human genes. Exons are shown as blue boxes; introns as lines between exons. Green squares denote the normal 5' (donor) splice sites; red squares represent the normal 3' (acceptor) splice sites. Green and red circles denote cryptic 5' and 3' splice sites, respectively. The broken blue wedge represents the site of mutation.

the consensus donor splice site have been frequently observed (Figure 7-13), with variable severity of the RNA splicing defect. Similarly, mutations in positions -3 and the polypyrimidine tract of the consensus acceptor splice site have been noted (Figure 7-13). In the majority of these cases, some normal splicing occurs and the defect is not severe. Utilization of cryptic splice sites leads to the production of abnormal mature mRNA with premature stop codons or to the inclusion of additional amino acids after translation (see Ref. (74) for examples and references cited therein).

Employing a neural network for splice-site recognition, Krawczak et al. (407) performed a meta-analysis of 478 disease-associated splicing mutations, in 38 different genes, for which detailed laboratory-based mRNA phenotype assessment had been performed. Inspection of the  $\pm 50$  bp DNA sequence context of the mutations revealed that exon skipping was the preferred phenotype when

the immediate vicinity of the affected exon-intron junctions was devoid of alternative splice sites. By contrast, in the presence of at least one such motif, cryptic splice-site utilization became more prevalent. This association was, however, confined to donor splice sites. Outside the obligate dinucleotide, the spatial distribution of pathological mutations was found to differ significantly from that of SNPs. Although disease-associated lesions clustered at positions -1 and +3 to +6 for donor sites and -3 for acceptor sites, SNPs were found to be almost evenly distributed over all sequence positions considered. When all putative missense mutations in the vicinity of splice sites were extracted from the HGMD for the 38 studied genes, a significantly higher proportion of changes at donor sites (37/152; 24.3%) than at acceptor splice sites (1/142; 0.7%) was found to reduce the neural network signal emitted by the respective splice site. It was estimated that some 1.6% of disease-causing missense

## HGMD Mutations in Intron splice sites (1-Dec-11)

FIGURE 7-13 Mutations in the consensus sequences of splice junctions recorded in the HGMD.

substitutions in human genes are likely to affect the mRNA splicing phenotype (196).

Other kinds of mutations in introns include those that cause the activation of cryptic splice sites (by altering a sequence so as to make it more similar to an authentic consensus splice site) or by creation of new splice sites (408). In both instances, new intron splice patterns occur with consequent introduction of stop codons or abnormal peptides after translation. These mutations do not completely abolish normal splicing and are therefore not associated with the absence of normal mature mRNA. A mutation in a lariat structure branchpoint (409) has been found in the *L1CAM* gene in a patient with X-linked hydrocephalus (410). By contrast, another mutation in intron 5 of the type 2 neurofibromatosis (*NF2*) gene created a consensus branchpoint sequence and led to the activation of a cryptic exon (411).

Some 98.7% of all splice sites in human genes conform to consensus sequences that include the invariant dinucleotides GT and AG at the 5' and 3' ends of the introns, respectively (412). Noncanonical sequences (e.g. GA-AG, GC-AG, and AT-AC) do however occur at human splice junctions, albeit much less frequently (<0.02%, 0.69%, and 0.05%, respectively). Some of

these noncanonical splice sites are nevertheless known to be utilized with high efficiency and may be conserved over quite long stretches of evolutionary time. Such sites have occasionally come to clinical attention when they have harbored mutations causing human inherited disease (413). Moreover, the utilization of a cryptic non-canonical donor splice site within exon 1 of the *HRPT2* gene in a case of familial isolated primary hyperparathyroidism as a consequence of a causative lesion in intron 1 of the gene has been reported (414). RNA isolated from EBV-transformed lymphoblastoid cell lines derived from the patients was utilized to demonstrate the consequences at the level of the mRNA phenotype (the loss of 30 bases from the mRNA transcript).

Single base-pair substitutions within “splicing enhancer” sequences may also perturb splicing by promoting exon skipping; examples include a mutation in intron 3 of the growth hormone (*GH1*) gene causing short stature (415) and a mutation in exon 5 of the adenosine deaminase (*ADA*) gene causing ADA deficiency (416). In patients with frontotemporal dementia with parkinsonism, three heterozygous mutations in a cluster of four nucleotides +13 to +16 of exon 10 of the microtubule-associated protein tau (*MAPT*) gene destabilized a

potential stem-loop structure that is probably involved in regulating the alternative splicing of exon 10. This caused more frequent use of the 5' splice site and an increased proportion of tau transcripts that include exon 10. The increase in exon 10+ mRNA increased the proportion of tau protein containing four microtubule-binding repeats, which is consistent with the neuropathology described in families with this type of frontotemporal dementia (417). One mutation found in the *ATM* gene causing ataxia-telangiectasia was a deletion of four nucleotides (GTAA) in intron 20 within an intron-splicing processing element (ISPE) that is complementary to U1 snRNA. This element mediates accurate intron processing and interacts specifically with U1 snRNP particles (418). Finally, the intronic prothrombin (*F2*) gene 19911A>G polymorphism influences splicing efficiency by altering a known functional pentamer CAGGG motif (419). Some nonsense mutations cause skipping of one or more exons, presumably during pre-mRNA splicing in the nucleus. This phenomenon has been termed “nonsense-mediated altered splicing” but its underlying mechanism is unclear. The first such mutation was described in the *FBN1* gene in Marfan syndrome (420). It is now recognized that any nucleotide substitution within exons (nonsense, missense, or translationally silent synonymous point mutation) that disrupts a splicing enhancer or silencer (ESE, enhancer splicing element; composite exonic regulatory element of splicing) or creates an exon splicing silencer (ESS) may affect either the pattern or the efficiency of mRNA splicing (89,421–423) (Figure 7-14). In exon 12 of the *CFTR* gene, about one quarter of synonymous variations result in exon skipping and, hence lead to the synthesis of an inactive CFTR protein (424). For reviews on the effects of exonic variants on splicing, and additional examples of such pathogenic mutations, see (425). It has been estimated that pathogenic effects of ~20% of mutations in the *MSH2* gene result from missense mutations that perturb splicing through the disruption of ESE sites. Similarly, the pathogenic effects of ~16% of missense mutations in the *MLH1* gene are thought to be

ESE related (426). Further, recent studies of exon splicing enhancer mutations have suggested that as many as 25% of known missense and nonsense mutations causing human inherited disease may alter functional splicing signals within exons (427,428). If this estimate is accurate, it suggests a much more widespread role for aberrant mRNA processing in causing human inherited disease than has hitherto been appreciated.

Splice-mediated insertional inactivation involving an *Alu* repeat was first reported by Mitchell et al. (429). Analysis of the ornithine  $\delta$ -aminotransferase (*OAT*) mRNA of a patient with gyrate atrophy revealed a 142 nucleotide insertion at the junction of exons 3 and 4. An *Alu* sequence is normally present in intron 3 of the *OAT* gene, 150 bp downstream of exon 3. The *Alu* sequence found in the cDNA was identical to this one, except that the patient was homozygous for a C→G transversion in the right arm of the *Alu* repeat which served to create a new 5' splice site. This activated an upstream cryptic 3' splice site [the poly(T) complement of the *Alu* poly(A) tail followed by an AG dinucleotide] and a new “exon,” containing the majority of the right arm of the *Alu* sequence, was recognized by the splicing apparatus and incorporated into the mRNA. The splice-mediated insertion of an *Alu* sequence in reverse orientation has also been reported in the *COL4A3* gene causing Alport syndrome (430). Deep intronic mutations, located at some considerable distance from splice sites and known splicing-related sequence elements, generally appear to comprise <1% of known splicing mutations (431–433). Such lesions often create novel splice sites thereby activating cryptic exons (“pseudoexons”). It should be appreciated that the <1% figure is very likely to be an underestimate owing to the inherent difficulty in detecting splicing mutations located outside of (and distant from) exon-intron splice junctions. Thus, for example, when the *NF1* gene was methodically screened for mutations that altered splicing, 5% of the identified lesions that altered splicing were deep intronic mutations (434). Among disease-causing lesions, inclusion of a pseudoexon as

**Exon Skipping due to mutations in enhancer splicing elements**

**FIGURE 7-14** Exon skipping due to nonsense, missense, and silent mutations in enhancer splicing elements (ESE). This element is shown as a darkened segment of the middle exon.

a consequence of cryptic splice-site activation appears to be the most common consequence of deep intronic mutation (435). If we also consider the deep intronic polymorphic variants that have the potential to confer susceptibility to disease (436–438), it is very likely that splicing-relevant intronic variation will have been seriously underascertained thus far.

### 7.4.5 RNA Cleavage-Polyadenylation Mutants

A number of examples of RNA cleavage-polyadenylation mutations have now been described (439). Those reported occur in the sequence AAUAAA, which is 10–30 nucleotides upstream of the polyadenylation site and is important for the endonucleolytic cleavage and polyadenylation of the mRNA. Mutation in this sequence of the  $\beta$ -globin (*HBB*) gene results in mild thalassemia (440). In these cases, normal polyadenylation and cleavage occurs at a level about 10% of normal. Alternative AAUAAA sites downstream of the mutated ones are used, resulting in larger mRNAs that are highly unstable. Other mutations near the poly(A) cleavage sequence may result in mRNA destabilization; one such mutation has been described 12 bp upstream of the AAUAAA sequence of the *HBB* gene in a patient with  $\beta$ -thalassemia (441).

The G>A mutation at the 3'-terminal nucleotide of the 3' UTR of the *F2* (prothrombin) gene mRNA gives rise to an elevated prothrombin plasma level and represents a common genetic risk factor for the occurrence of thromboembolic events. This mutation creates an inefficient 3' end cleavage signal and represents a gain-of-function mutation, causing increased cleavage site recognition, increased 3' end processing and increased mRNA accumulation and protein synthesis (442,443).

### 7.4.6 Mutations in MicroRNA-Binding Sites

MicroRNAs (miRNAs) posttranscriptionally down-regulate gene expression by binding to complementary sequences on the 3' UTRs of their cognate mRNAs, thereby inducing either mRNA degradation or translational repression. Over 700 human miRNAs have so far been identified but many more probably still remain to be discovered. These miRNAs are each likely to down-regulate a large number of different target mRNAs.

The first reported pathological mutation in an miRNA-binding site was a G→A transition in a binding site for miR-189 within the 3' UTR of the *SLITRK1* gene of two apparently unrelated Tourette syndrome patients (444). Experimental confirmation of the functional effect of this mutation came from the demonstration that, in the presence of miRNA-189, in vitro constructs bearing the 3' UTR mutation served to increase repression of a reporter gene by comparison with the wild type. A further example of a functional miRNA-target site variation involves an SNP in the 3' UTR of the human *AGTR1*

gene; although the variant allele is not downregulated by miR155, it has been associated with hypertension in numerous studies (445). An increasing number of genetic variants located in microRNA target sites are being reported, either causing or associated with an increased risk of inherited disease (446–450).

### 7.4.7 Mutations in Nonprotein-Coding Genes

In contrast to the plethora of mutations identified in protein-coding genes, the identification of mutations in nonprotein-coding genes is still very much in its infancy (451). A number of disease-causing or disease-associated mutations have already been reported in various small nucleolar RNA genes (452,453) and miRNA genes (454–457). In addition, mutations have also been documented in the longer noncoding RNA genes *XIST*, *TERC*, *H19*, and *RMRP* (see HGMD for details).

A putative pathological mutation has been described in a “gene” encoding a paternally expressed antisense transcript of the *GNAS* complex locus (*GNASAS*) (458), whereas a functional polymorphism has been reported within an enhancer at the 30 end of the *CDKN2BAS* “gene,” which encodes an antisense RNA transcript (459). A *CRYGE1* pseudogene-reactivating mutation associated with hereditary cataract formation (460) probably also falls into this category. The above examples are likely to comprise only the tip of a fairly large iceberg that still remains essentially unexplored. Thus, for example, both SNP and CNV are likely to impact significantly on miRNA gene expression with myriad potential pathological consequences (446).

### 7.4.8 Mutations in Noncoding Regions of Functional Significance

By adopting a gene-centric view, we have until now largely ignored the extensive nonprotein-coding portion of the human genome in our quest for mutations of pathological significance. As a consequence, we have not only seriously underestimated the extent of the functional component of the genome, but may also have overlooked many mutations within this genomic “dark matter” (461). In both the human and the mouse genomes, many noncoding regions exhibit a similar level of evolutionary conservation to that evident in protein-coding regions (462,463). As yet, however, little is known of the effect that mutations in these regions might have on either the phenotype or on overall fitness. Studies of the most evolutionarily conserved noncoding regions have yielded results that are consistent with the view that most mutations in noncoding regions are only slightly deleterious (463,464).

To obtain a first, necessarily rather crude, estimate of the contribution of variation in human noncoding sequences to phenotypic and/or disease traits, Visel

et al. (465) performed a meta-analysis of ~1200 SNPs that have been identified as the most significantly associated variants in published GWAS. They found that, in 40% of cases, neither the SNP in question nor its associated haplotype block overlapped with any known exons. These authors, therefore, concluded that in at least one-third of detected disease associations, variation in noncoding sequence rather than coding sequence could have causally contributed to the trait in question. We suspect that this could be because the common disease-common variant's hypothesis (466) may be much more likely to apply to noncoding sequence than to coding sequence, owing to the selectional constraints impacting on sufficiently frequent functional variation in the latter. In similar vein, others have also estimated that 39–43% of trait/disease-associated SNPs in GWAS are located within intergenic regions (467,468). This notwithstanding, it should be appreciated that any given variant apparently detected within a noncoding region may actually reside within a hitherto undiscovered exon (469). We should, however, also be aware that rare variants, in *cis* to those found to be associated with a given disease or trait in GWAS studies, may simply by chance give rise to “synthetic associations” that are then attributed to much more common variants (470).

In the context of identifying genetic variants responsible for human inherited disease, Cooper et al. (4) have argued that it will become increasingly important to consider functional elements in the genome (the “functionome”) rather than simply genes *per se*. We employ the term “functionome” here to describe the totality of the biologically functional nucleotide sequences in the human genome, irrespective of whether they are associated with genes or not. Because conserved noncoding sequences in the human genome appear to be ~10-fold more abundant than known genes (471), it is likely that (1) currently known mutations within coding regions are unlikely to be fully representative of the universe of pathological mutations and (2) a whole new grouping of disease-causing mutations may await identification and characterization. Once again, a paradigm shift in our thinking may well be required if we are to maximize the potential of the emerging high-throughput technology to detect new (hitherto latent) types of human gene mutation.

The above notwithstanding, it is rather unlikely that the functional nonprotein-coding portion of the human genome will prove to be quite as mutation-dense as the protein-coding portion. For most inherited disorders, the mutation detection rate is already fairly high (490%), although this success rate is often achieved by combining different mutation detection methodologies, for example, to screen for exon deletions and CNVs as well as more subtle lesions (472). At least some of the “missing lesions” may nevertheless be found by screening extragenic functional elements.

### 7.4.9 Cap Site Mutations

Transcription of the mRNA is initiated at the so-called cap site, which is protected from exonucleolytic degradation by the addition of  $\alpha$ -methylguanine. An A to C transversion at the cap site of the  $\beta$ -globin (*HBB*) gene was found in a patient with  $\beta$ -thalassemia (473). It is not, however, clear if this mutation causes reduced transcription or abnormal initiation of transcription since C is found in 6% of transcriptional initiation sites (474) (the most common nucleotide [76%] at position +1 is A). A functional (C/A) polymorphism of the transcriptional initiation site has been noted in the *APOH* gene; the rarer A allele displayed a carrier frequency of 0.12 and was associated with markedly reduced plasma  $\beta$ 2 glycoprotein I (475).

### 7.4.10 Mutations in 5' UTRs

Sequence motifs in the 5' UTRs of genes are thought to play a role in controlling the translation of the encoding mRNA. The phenotypic effects of lesions in 5' UTRs and their clinical consequences have been reviewed (476). Mutations in the iron response element (IRE) in the 5' UTR of the ferritin (*FTH1*) gene interfere with the post-transcriptional regulation of ferritin synthesis by decreasing the affinity of IRE for IRE-binding protein (477). By contrast, decreases in the steady-state level of  $\beta$ -globin (*HBB*) mRNA have been noted in association with a single base deletion at position +10, a G-to-A substitution at position +22, a C-to-G transversion at position +33, and a 4 bp deletion (AAAC) at position + (40–43) in the *HBB* 5' UTR (478–480).

### 7.4.11 Mutations in 3' Regulatory Regions

Sequences in the 3' regulatory regions (3' RRs) of genes are known to be involved in controlling mRNA cleavage/polyadenylation and determining mRNA stability, nuclear export, intracellular localization, and translational efficiency. Although such regions are rich in regulatory elements, relatively few pathological mutations have been reported (439,481). Although only ~0.2% of mutations currently logged in HGMD are located within 3' RRs, this is likely to represent a rather conservative estimate of their actual prevalence. A typical example is the G→A transition 69 nucleotides downstream of the polyadenylation site of the  $\delta$ -globin (*HBD*) gene causing  $\delta$ -thalassemia (482); the mutation occurs within a GATA motif and serves to increase the binding affinity of the sequence for erythroid-specific DNA binding protein.

In an attempt to study 3' RR mutations systematically, Chen et al. (439,483) performed a systematic analysis of disease-associated variants in the 3' RRs of human protein-coding genes. A total of 121 3' RR variants in 94 human genes were collated including 17 mutations

in the upstream core polyadenylation signal sequence (UCPAS), 79 in the upstream sequence (USS) between the translational termination codon and the UCPAS, 6 in the left arm of the “spacer” sequence between the UCPAS and the pre-mRNA cleavage site, 3 in the right arm of the “spacer” sequence or downstream core polyadenylation signal sequence, and 7 in the DSS of the 3'-flanking region. All the UCPAS mutations and the rather unusual cases of *DMPK*, *SCA8*, *FCMD*, and *GLA* mutations were found to exert a significant effect on the mRNA phenotype and the majority cause monogenic disease. By contrast, most of the remaining variants were polymorphisms, were found to exert a comparatively minor influence on mRNA expression, but may predispose to, protect from, or modify complex clinical phenotypes. The systematic study of these lesions permitted the identification of consistent patterns of secondary structural change that promise to allow the discrimination of nonfunctional USS variants from their functional counterparts.

#### 7.4.12 Translational Initiation Codon Mutations

Mutations in the ATG translational initiation codon have been reported in quite a wide variety of disorders (e.g. Ref. (484)). Instances of substitutions in all three nucleotides have been observed in  $\beta$ -thalassemia, Norrie disease, albinism, phenylketonuria, McArdle disease, and Albright osteodystrophy among others. Indeed, a total of 405 mutations within ATG translational initiation codons are recorded in HGMD representing ~0.7% of the total number of reported coding sequence mutations causing human inherited disease. Almost invariably, the mutation leads to severe reduction of steady-state mRNA levels similar to that associated with nonsense mutations. The mutant mRNA is presumably not translated. The first AUG codon occurs in the context of the so-called Kozak consensus sequence GCCA/GCCAUGG, which is thought to be recognized by the 40S ribosomal subunit (485). Mutations at the initiator methionine ATG may completely abolish translation; however, there are alternative possibilities, namely utilization of the mutant ATG with much reduced efficiency or translational initiation at the next available ATG codon. A C/T polymorphism immediately 5' to the ATG codon within the Kozak sequence of the *CD40* gene is thought to influence translation efficiency (486).

Some diseases are caused by mutations that perturb the initiation step of translation by changing the context around the start AUG codon or introducing upstream AUG codons (see Ref. (487) for review). The scanning mechanism provides a framework for understanding the effects of these changes in mRNAs. The scanning mechanism refers to the entry of the small ribosomal subunit at the (usually capped) 5' end of the mRNA and linear migration until an AUG codon is

encountered. Mutational mechanisms such as (i) reinitiation at an internal start codon (e.g. thrombopoietin, *TPO*) and (ii) leaky scanning (as in the case of the *Rx/rax* gene underlying the mouse eyeless mutation) probably account for such cases.

Naturally occurring mutations in the GCCA/GCCAUGG motif include (for the numbering of the mutant nucleotide, the A of the AUG codon is +1; see references in Ref. (487)): (i) +4 G-to-A in the androgen receptor (*AR*) gene in a family with partial androgen insufficiency; (ii) -1 C-to-T transition in the  $\alpha$ -tocopherol transfer protein (*TTPA*) gene in a family with vitamin E deficiency; (iii) a 2 nt deletion causes an A-to-C change at position -3 of the  $\alpha$ -globin gene (*HBA*) in a patient with  $\alpha$ -thalassemia; (iv) -3 A-to-T transversion in the mouse *Pax6* gene causes defects in eye development; and (v) -3 G-to-C somatic mutation in the *BRCA1* gene in one case of highly aggressive sporadic breast cancer. It is not surprising that most of the naturally occurring mutations involve positions -3 and +4, the positions wherein experimentally induced mutations have the strongest effect.

A meta-analysis of 405 unique (HGMD-derived) single base-pair substitutions, located within the ATG translation initiation codons of 255 different genes, reported to cause human genetic disease has been performed (488). Although these lesions comprised only 0.7% of coding sequence mutations in HGMD, they nevertheless were 3.4-fold overrepresented as compared to other missense mutations. The distance between a translation initiation codon and the next downstream in-frame ATG codon was significantly greater for genes harboring ATG codon mutations than for the remainder of genes in HGMD (control genes). This suggests that the absence of an alternative ATG codon in the vicinity of an ATG translation initiation codon increases the likelihood that a given ATG mutation will come to clinical attention. An additional 42 single base-pair substitutions in 37 different genes were identified in the vicinity of ATG translation initiation codons (positions -6 to +4, comprising the Kozak consensus sequence). These substitutions were however not evenly distributed, being significantly more abundant at position +4. Finally, contrary to the authors' initial expectation, the match between the original translation initiation codon and the Kozak consensus sequence was significantly better (rather than worse) for genes harboring ATG codon mutations than for the HGMD control genes (488).

#### 7.4.13 Termination Codon (“Nonstop”) Mutations

“Nonstop” mutations are single base-pair substitutions that occur within translational termination (stop) codons, which can lead to the continued and inappropriate translation of the mRNA into the 3'-UTR. The classic example of a termination codon mutant is the case of the  $\alpha_2$ -globin Constant Spring, with a mutation in the normal

stop codon; this substitution leads to incorporation of an additional 31 amino acid residues in the  $\alpha_2$ -globin polypeptide chain (489). The resulting protein is unstable and does not interact properly with the  $\beta$ -globin chains of hemoglobin. Some 119 mutations within Term codons (in 87 different genes) have been recorded in HGMD, representing ~0.2% of all missense/nonsense mutations.

A meta-analysis of these 119 nonstop mutations noted a paucity of alternative in-frame stop codons in the immediate vicinity (0–49 nucleotides downstream) of the mutated stop codons as compared with their control counterparts (490). This implies that at least some nonstop mutations with alternative stop codons in close proximity will not have come to clinical attention, possibly because they will have given rise to stable mRNAs (not subject to nonstop mRNA decay) that are translatable into proteins of near-normal length and biological function. A significant excess of downstream in-frame stop codons was, however, noted in the range 150–199 nucleotides from the mutated stop codon (490). The authors speculated that recruitment of an alternative stop codon at greater distance from the mutated stop codon might trigger nonstop mRNA decay, thereby decreasing the amount of protein product and yielding a readily discernible clinical phenotype.

#### 7.4.14 Frameshift Mutations

A large number of frameshift mutations have been described in numerous disease-related genes. All lead to altered translational termination with abnormal polypeptide chains after the frameshifts; severe phenotypes are usually seen (491). Frameshifts occur with micro-deletions or micro-insertions and exon skipping. The mechanisms underlying these mutations were discussed earlier in this chapter.

#### 7.4.15 Nonsense Mutations

Nonsense mutations give rise to premature termination of translation and truncated polypeptides. They account for ~11% of all described gene lesions causing human inherited disease and ~20% of disease-associated single base-pair substitutions affecting gene coding regions (492). Pathological nonsense mutations resulting in TGA (38.5%), TAG (40.4%), and TAA (21.1%) occur in different proportions to naturally occurring stop codons (492). Of the 23 different nucleotide substitutions giving rise to nonsense mutations, the most frequent are CGA → TGA (21%; resulting from methylation-mediated deamination) and CAG → TAG (19%) (492). The differing nonsense mutation frequencies are largely explicable in terms of variable nucleotide substitution rates such that it is unnecessary to invoke differential translational termination efficiency or differential codon usage. Nonsense mutations are usually associated with a reduction in the steady-state level of cytoplasmic mRNA (493).

This mechanism of “NMD” is responsible for the degradation of mRNAs that contain a premature termination codon at a position at least 50 nt upstream of an exon–exon boundary (494) but it is not universal (495). One or more parameters could be affected: the transcription rate, the efficiency of mRNA processing or transport to the cytoplasm, or mRNA stability.

In the majority of described instances of nonsense mutations, the resulting disorders are recessive in nature as a consequence of the haploinsufficiency resulting from the NMD-induced absence of the truncated proteins (which ensures that such polypeptides do not interfere with the function of the wild-type protein). Nonsense mutations that do not elicit NMD can, however, give rise to a dominant negative condition (e.g. mutations in the *SOX10* gene causing Waardenburg Shah syndrome; (496)). Since for NMD to be activated, the nonsense mutation must reside at least 50–55 nt upstream of an exon–exon boundary, it follows that the precise location of the nonsense mutation could be an important factor in predicting the pathogenicity of that lesion. By way of example, nonsense mutations within the last exon of the human  $\beta$ -globin (*HBB*) gene do not elicit NMD. As a consequence, the truncated  $\beta$ -globin product has near-normal abundance, fails to associate properly with  $\alpha$ -globin, and hence gives rise to a dominantly inherited form of  $\alpha$ -thalassemia (24). Different nonsense mutations within the same gene may thus be associated with different clinical phenotypes depending on whether or not NMD is activated. Another example of this is provided by a nonsense mutation (Q37X) in the *DAX1* gene of an adrenal hypoplasia congenita patient; this lesion is associated with a milder-than-expected clinical phenotype on account of the expression of a partially functional, amino terminal-truncated DAX1 protein synthesized from an alternative in-frame translational start site at Met83 (497). In a recent meta-analysis, the proportion of known disease-causing nonsense mutations predicted to elicit NMD was found to be significantly higher than among nonobserved (potential) nonsense mutations, implying that nonsense mutations that elicit NMD are more likely to come to clinical attention (492). In practical terms, the observation of greatly reduced or absent cytoplasmic mRNA associated with nonsense mutations has important implications for mutation screening. Thus, attempts to obtain mRNA for RT-PCR and mutation detection may result in amplification of nucleic acid from only the non-nonsense mutation-bearing allele. Nonsense mutations in the factor VIII (*F8*) gene (hemophilia A) and fibrillin (*FBN1*) gene (Marfan syndrome) have been associated with the skipping of exons containing these mutations (240,420) and this observation has now been extended to other genes; exon skipping is either complete or partial. The mechanism underlying this phenomenon is unknown although a number of intriguing models have been proposed (498).

Some genes are characterized by numerous nonsense mutations but relatively few if any missense mutations (e.g. *CHM*), whereas other genes exhibit many missense mutations but few if any nonsense mutations (e.g. *PSEN1*). Genes in the latter category have a tendency to encode proteins characterized by multimer formation (492). Consistent with the operation of a clinical selection bias, genes exhibiting an excess of nonsense mutations are also likely to display an excess of frameshift mutations (492). Recently, an example of the spontaneous read-through of a premature termination codon was reported in a patient who was a compound heterozygote for two nonsense mutations in the *LAMA3* gene (R943X/R1159X) (499). The patient, who presented with junctional epidermolysis bullosa, was expected to die as a consequence of harboring these nonsense mutations but was “rescued” by spontaneous read-through of the R943X-bearing allele. This patient’s full-length R943X-bearing *LAMA3* mRNA escaped nonsense-mediated decay, thereby ensuring near-normal *LAMA3* mRNA and laminin- $\alpha 3$  protein levels. The genetic context of the *LAMA3* mutation R943X was found to be close to a hypothetical consensus sequence for optimal premature termination codon read-through.

#### 7.4.16 Unstable Protein Mutants

Missense mutations can cause abnormal protein folding and are, therefore, associated with reduced expression owing to instability of the protein. Reviews of mutations that affect protein stability can be found in Refs. (500,501). For proteins that circulate in body fluids, most mutations are associated with “CRM negative” status in which the amount of protein correlates with the amount of activity or “CRM reduced” status in which the amount of activity is still lower than the amount of protein produced. Many such mutations have been seen in factor VIII causing mild/moderate hemophilia A (76).

The nature of the biophysical properties of amino acid substitutions in p53 that increase their likelihood of coming to clinical attention has been explored (502); these include solvent inaccessibility, the number of adverse steric interactions introduced, and a reduction in H-bond number. This study was extended by modeling *in silico* all amino acid replacements that could potentially have arisen from an inherited single base-pair substitution in five human genes encoding arylsulfatase A (*ARSA*), antithrombin III (*SERPINC1*), protein C (*PROC*), phenylalanine hydroxylase (*PAH*), and transthyretin (*TTR*) (386). A total of 9795 possible mutant structures were modeled and 20 different biophysical parameters assessed. Comparison with the HGMD-derived spectra of 469 clinically detected mutations indicated that several types of mutation-associated change affected protein function, including the energy difference between wild-type and mutant structures, solvent accessibility of the mutated residue, and distance from the binding/

active site. These parameters are considered to be important in protein folding which adds support to the view that many missense mutations come to clinical attention by virtue of their consequences for protein folding and stability (503,504).

#### 7.4.17 Mutations in Remote Gene Regulatory Elements

In the  $\beta$ -globin gene cluster, a regulatory region about 10kb upstream of the  $\epsilon$ -globin (*HBE*) gene has been identified that is capable of directing a high level of position-independent  $\beta$ -globin gene expression (505). This region, termed the locus control region (LCR), is thought to organize the entire 60kb  $\beta$ -globin gene cluster into an active chromatin domain and to enhance the transcription of individual globin genes (506). A similar LCR is also present in the  $\alpha$ -globin gene cluster and other gene clusters (507). Deletions of the LCR in the  $\beta$ -globin gene cluster result in silencing of the  $\beta$ -globin (*HBB*) and other genes of the cluster, even although the coding regions of these genes are still intact (401). A particular 25kb deletion, known as Hispanic  $\gamma\delta\beta$ -thalassemia, which deletes sequences 9.5–39kb upstream of the  $\epsilon$ -globin (*HBE*) gene including the LCR renders the *HBB* gene 60kb downstream of the deletion nonfunctional (508). This extraordinary effect of the deletion of the LCR is thought to be due to an altered (DNase I-resistant) state of chromatin associated with nonfunctional genes. Several other examples of similar deletions in the LCR of the  $\alpha$ -globin gene cluster have been reported (509).

Several other examples of remote regulatory elements have come to attention as a consequence of their ablation by gross deletions located at some considerable distance (from 10kb to several megabases) from the genes whose expression they disrupt (150). For instance, a 960-kb deletion of noncoding sequence, lying between 1.477Mb and 517kb upstream of the *SOX9* gene gives rise to the acampomelic form of campomelic dysplasia (510). Such pathological deletions, however, are not necessarily always so large. Indeed, a 7.4kb deletion, located 283kb upstream of the *FOXL2* gene, has been identified as a cause of blepharophimosis syndrome; it disrupts a long noncoding RNA (*PISRT1*) as well as eight conserved noncoding sequences (511). For some conditions, such lesions may actually occur quite frequently, as in the case of the *SHOX* gene where ~22% of Leri–Weill syndrome patients and ~1% of individuals with idiopathic short stature harbor a micro-deletion spanning the upstream enhancer region that leaves the coding region of the *SHOX* gene intact (512).

Over the last few years, a number of other examples of mutations in remote promoter elements have been reported. These include a total of nine mutations within a 1-kb region (termed the long-range or limb-specific enhancer) ~979kb 5' to the transcriptional initiation site of the sonic hedgehog (*SHH*) gene (513)

and a T>C transition 1.44Mb upstream of the *SOX9* gene associated with cleft palate/Pierre Robin sequence (514). Far upstream polymorphic variants that influence gene expression and that are relevant to disease are also beginning to be documented. Thus, for example, the C>T functional SNP 14.5 kb upstream of the *IRF6* gene, associated with cleft palate, alters the binding of transcription factor AP-2 $\alpha$  (515). Similarly, a functional SNP ~6kb upstream of the  $\alpha$ -globin-like *HBM* gene serves to create a binding site for the erythroid-specific transcription factor GATA1 and interferes with the activation of the downstream  $\alpha$ -globin genes (402). A functional SNP ~335 kb upstream of the *MYC* gene increases the risk of colorectal and prostate cancer by increasing the expression of the *MYC* gene by altering the binding strength of transcription factors TCF4 and/or TCF7L2 to a transcriptional enhancer (516–519). Finally, in the context of pointing out the shortcomings of the gene-centric approach to mutation detection, we should be aware that functional SNP rs4988235, located 13.9kb upstream of the lactase (*LCT*) gene and associated with adult-type hypolactasia, actually resides deep within intron 13 (c.19171+326C>T) of the *MCM6* gene (520–522). Given that up to 5% of quantitative trait loci for gene expression lie >20kb upstream of transcriptional initiation sites (523), many more far upstream polymorphic variants that influence gene expression are likely to be identified in the coming years.

Rather fewer pathological mutations are known to be located at a considerable distance downstream of human genes. One example is the C>G transversion 2528 nt 3' to the term codon of the *CDK5R1* gene, which has been postulated to play a role in nonspecific mental retardation (524). Perhaps more dramatic is the A>G SNP (rs2943641), 565981bp 3' to the Term codon of the *IRS1* gene, which is associated with type 2 diabetes, insulin resistance, and hyperinsulinemia; the G allele was found to be associated with a reduced basal level of *IRS1* protein (525).

In the light of the above, it can be seen that the underascertainment of disease-associated mutations within regulatory regions is likely to be quite substantial but can potentially be rectified by emerging high-throughput entire genome sequencing protocols.

#### 7.4.18 Cellular Consequences of Trinucleotide Repeat Expansions

Trinucleotide repeat expansion has been discussed earlier. In the case of fragile X, the (CGG) $_n$  repeat is located in the 5' UTR of the *FMR1* gene, and its expansion to full mutation results in hypermethylation of the promoter region, loss of transcription, and hence silencing of the gene (526). Loss of the encoded protein, fragile X mental retardation protein (FMRP), which is thought to play a role in dendritic mRNA transport and translation, is responsible for the classical fragile X syndrome

phenotype. Gene inactivation can also be caused by altering the spacing of promoter elements from the transcriptional start site as in the case of the 12mer repeat expansion in the *CSTB* gene (126).

When the trinucleotide repeat lies within the gene-coding region as in Huntington disease, its expansion results in an abnormal protein with a gain of function due to the enlargement of the polyglutamine tract. Mutant huntingtin exerts its pathological effects via abnormal protein aggregation, transcriptional dysregulation, mitochondrial dysfunction, excitotoxicity, and abnormal cellular trafficking, leading to neuronal loss particularly in the dorsal substratum (527).

Another example of a gain-of-function mutation is provided by the expansion of the CTG repeat in the 3' UTR of the *DMPK* gene causing type 1 myotonic dystrophy (DM1). This does not abolish transcription but rather causes nuclear retention of RNA transcripts leading to the transcriptional dysregulation of other genes (528). CTG expansion appears to lead to the sequestration of cellular RNA-binding proteins, which in turn gives rise to the abnormal splicing of multiple transcripts (529). DM1 thus exemplifies a disease whose mechanistic basis lies at the RNA level.

#### 7.4.19 Mutations That Give Rise to Inappropriate Gene Expression

HPFH and hereditary persistence of  $\alpha$ -fetoprotein (HPAFP) are two clinical conditions that are prototypes for the inappropriate expression of  $\gamma$ -globin (*HBG1* and *HBG2*) and  $\alpha$ -fetoprotein (*AFP*) genes, respectively. Normally, the levels of fetal hemoglobin (HbF;  $\alpha_2\gamma_2$ ) in adult life are very low, as there is a switch from fetal to adult hemoglobin during the perinatal period. Similarly, AFP is produced at high level in fetal liver but declines rapidly after birth. In HPFH and HPAFP, however, the levels of HbF and AFP, respectively, are inappropriately high in adult life. This is often due to single nucleotide substitutions in the promoter regions of the *HBG2*, *HBG1*, or *AFP* genes. A considerable number of mutations that occur in the region -114 to -202 of the  $\gamma$ -globin genes have been characterized and presumably cause persistent expression of their corresponding genes (401). A similar situation has been observed with a -119 mutation in the *AFP* gene (530). These mutations occur within DNA binding motifs for transcriptional regulators. A very interesting mutational mechanism has been proposed for facioscapulohumeral muscular dystrophy (FSHD), a common autosomal dominant myopathy associated with a typical pattern of muscle weakness. Most FSHD patients carry a large deletion of a 4q35-located polymorphic D4Z4 macrosatellite repeat array and present with fewer than 11 repeats whereas normal individuals possess between 11 and 150 repeats (531). An almost identical D4Z4 repeat array is present at 10q26 (532) and the high sequence homology between these two

arrays can cause difficulties in molecular diagnosis. Each 3.3 kb D4Z4 repeat contains a *DUX4* (double homeobox 4) gene that, among others, is activated on contraction of the 4q35 D4Z4 array due to the induction of chromatin remodeling of the 4qter region. An increasing number of 4q subtelomeric sequence variants are now recognized, although FSHD only occurs in association with three “permissive” haplotypes, each of which are associated with a polyadenylation signal located immediately distal of the last D4Z4 repeat (533). This poly-A signal stabilizes any *DUX4* mRNAs transcribed from this most distal D4Z4 repeat in FSHD muscle cells. Synthesis of both the *DUX4* transcripts and the protein in FSHD muscle cells induces significant cell toxicity. *DUX4* is a transcription factor that targets several genes which results in a deregulation cascade that inhibits myogenesis, sensitizes cells to oxidative stress and induces muscle atrophy, thereby recapitulating many of the key molecular features of FSHD (534).

#### 7.4.20 Position Effect in Human Disorders

In several instances, a DNA alteration is found well outside the putative gene that is primarily involved with a disease. Mutations acting by “positional effect” are those in which the transcription unit and minimal promoter of the gene remain intact, but there is a nearby alteration that influences gene expression (535). These positional effect DNA lesions may involve distal promoter regions, enhancer/silencer elements, or changes in the local chromatin environment. The positional effect could be up to several megabases away from the gene of interest. The examples of the LCR in the  $\beta$ -globin gene cluster and the transcriptional repressor D4Z4 in FSHD are provided elsewhere in this chapter. Most of the position effects are due to chromosomal rearrangements that frequently lead to alteration of the chromatin environment of the gene. Possible mechanisms which may lead to a positional effect include the following: (i) The rearrangement separates the transcription unit from distant *cis*-regulatory elements (enhancer removal results in gene silencing, whereas silencer removal results in inappropriate gene activation); (ii) juxtaposition of the gene with an enhancer element from another part of the genome; (iii) removal of an insulator or boundary element may also lead to inappropriate gene silencing; (iv) enhancer competition of DNA sequences that were juxtaposed to the gene; (v) positional effect variegation in which the chromosomal rearrangement causes the juxtaposition of an euchromatic gene with a region of heterochromatin.

Some examples of positional effect mutations due to translocation breakpoints include genes *PAX6* in aniridia (536), *SOX9* in campomelic dysplasia (537,538), *POU3F4* in X-linked deafness (539), *HOXD* complex in mesomelic dysplasia (540), *FOXL2* in blepharophimosis/ptosis/epicanthus inversus syndrome (BPES) (541,542),

and the *SHH* gene in preaxial polydactyly (543). In these cases, the translocation breakpoints may be in excess of a megabase away from the inappropriately expressed/silenced gene. Indeed, in one example of campomelic dysplasia, the breakpoint maps ~1.3 Mb downstream of the *SOX9* gene, making this the longest-range position effect so far found (538). For a recent review of position effect mutations, see (544).

It is likely that in the majority of cases, the position effect involves a highly conserved *cis*-acting regulatory element. These *conserved noncoding elements* (CNCs; also termed multiple-species conserved sequences; conserved non-genic sequences; the most highly conserved are also called ultra-conserved elements) comprise approximately 1–2% of the human genome and represent potential targets for pathogenic mutations (545–549). An example of such a lesion is provided by the 52 kb deletion of a large noncoding region downstream of the sclerostin (*SOST*) gene in patients with van Buchem disease, leading to altered expression of the *SOST* gene (550). The deletion disrupts a bone-specific enhancer element that drives *SOST* gene expression.

Pathogenic mutation may also occur in nonconserved elements that could become functional after the introduction of the mutant sequence. This pathogenetic mechanism has been described underlying a variant form of  $\alpha$ -thalassemia. Affected individuals from Melanesia have a gain-of-function regulatory single nucleotide polymorphism (rSNP) in a non-genic region between the  $\alpha$ -globin genes and their upstream regulatory elements. The rSNP creates a new promoter-like element that interferes with the normal activation of all downstream  $\alpha$ -like globin genes (402).

#### 7.4.21 Position Effect by an Antisense RNA

An individual with an inherited  $\alpha$ -thalassemia has been described who has a deletion that results in a truncated, widely expressed gene (*LUC7L*) becoming juxtaposed to a structurally normal  $\alpha$ -globin (*HBA2*) gene. Although it retained all of its local and remote *cis*-regulatory elements, expression of the *HBA2* gene was nevertheless silenced and its CpG island became completely methylated at an early stage during development. The antisense RNA of the *LUC7L* gene appears to have been responsible for the silencing of the *HBA2* gene (551).

#### 7.4.22 Abnormal Proteins Due to Fusion of Two Different Genes

The translation of fusion genes results in novel proteins with different or abnormal properties from their parent polypeptides. Fusion genes are either the result of homologous unequal crossing-over or the junction sequences at breakpoints of chromosomal translocations. Hemoglobin Lepore, a fusion of  $\delta$ - and  $\beta$ -globin genes, is the prime example of the first mechanism. Other examples

of abnormal fusion genes due to unequal crossover include the case of glucocorticoid-suppressible hyperaldosteronism (GSH), an autosomal dominant form of hypertension, caused by oversecretion of aldosterone (552); some GSH patients have hybrid genes between *CYP11B1* and *CYP11B2*, two highly homologous cytochrome P450 genes on 8q22. The hybrid gene contains the regulatory elements of *CYP11B1*, expressed in the adrenal gland, and the 3' coding region of *CYP11B2*, which is essential for aldosterone synthesis. Another example is the case of abnormalities of color vision resulting from fusion of the green and red color pigment (*RCP*, *GCP*) genes (553). Recombination between the Kallmann gene on Xp22.3 (*KALX*) and its homolog (*KALY*) at Yp11.21 results in a fusion gene that is transcriptionally inactive and is associated with Kallmann syndrome secondary to an X;Y translocation. Finally, Francis et al. (554) identified a large atypical hemolytic uremic syndrome family in whom a deletion occurred through MMEJ rather than by NAHR. The deletion resulted in the formation of a *CFH/CFHR3* hybrid gene. The protein product of this gene, a 24 short consensus repeat protein, was found to be secreted at slightly lower levels than wild-type factor H, but the decay accelerating and cofactor activities of this protein were significantly impaired. A growing number of hematologic malignancies are associated with abnormal fusion proteins, the genes of which are found at the breakpoints of chromosomal translocations. One of the first reported examples was the case of fusion of the *BCR* and *ABL* genes in the *t* (9;22) known as Philadelphia (Ph) chromosome in chronic myelogenous leukemia. The *BCR* gene is on chromosome 22 and the *ABL* gene is on chromosome 9; after the translocation junction, a fusion gene is created with the promoter elements of the *ABL* gene and the 3' half of the *BCR* gene (555). A new abnormal protein is detected in the leukemia cells, the abnormal function of which probably contributes to the malignant phenotype. Another example is the case of Ewing sarcoma (a solid tumor of bone) in which an 11;22 translocation results in a fusion of the *FLI1* gene on 11q24 with the *EWS* gene on 22q12 (556) and for a classical review see (557). Fusion genes can be readily identified by PCR and can serve either as diagnostic indicators for relapse in the disorders concerned or as indicators of the need for an alternative therapeutic regimen.

#### 7.4.23 Mutations in Genes Involved in Mismatch Repair Associated with Genomic Instability in the Soma

The study of somatic mutation is extremely important both for the study of cancer (558) and for other diseases such as paroxysmal nocturnal hemoglobinuria (559). Mutations that lead to abnormal or abolished function of genes encoding for proteins involved in DNA mismatch repair are of particular importance because they lead to accumulation of mutations throughout the

genome. For example, some forms of hereditary nonpolyposis colon cancer (HNPCC), which may account for up to 10% of colon carcinoma, are due to mutations in genes such as *MSH2* or *MLH1* that encode mismatch repair proteins (560–562). In families with mutations in these genes, the DNA of tumor tissue shows considerable instability as detected by the generation of new alleles for numerous DNA polymorphic markers (563). One of the genes affected by the genomic instability is that encoding the type II transforming growth factor- $\beta$  (TGF- $\beta$ ) receptor, (*TGFB2R*) which has a run of 10 adenines in its coding region. This run of As is altered, resulting in a frameshift and absence of the receptor, which in turn releases the cell from TGF- $\beta$  inhibitory effects and contributes to malignancy (564). The discovery and further study of genes of the mutation repair system will enhance our understanding of both germline and somatic mutations.

#### 7.4.24 Comparison of Germline and Somatic Mutational Spectra

To date, relatively few studies have attempted to compare the germline and somatic mutational spectra for the same genes. This notwithstanding, the mutational mechanisms underlying single base-pair substitutions (565,566), micro-deletions, and micro-insertions (566–568), and even gross gene rearrangements (569,570) often appear to exhibit similarities between the germline and the soma. Ivanov et al. (571) performed a comparison of somatic, germline, shared (found in both soma and germline), and somatic recurrent mutational spectra for 17 human tumor suppressor genes, which focused upon missense single base-pair substitutions and micro-deletions/micro-insertions. The somatic and germline mutational spectra for these genes were similar in relation to C.G>T.A transitions but differed with respect to the frequency of A.T>G.C, A.T>T.A, and C.G>A.T substitutions. Shared missense mutations were found to be characterized by higher mutability rates, greater physicochemical differences between the wild-type and mutant residues, and a tendency to occur in evolutionarily conserved residues and within CpG/CpHpG oligonucleotides. Mononucleotide runs of  $\geq 4$  bp were identified as hotspots for shared micro-deletions/micro-insertions.

#### 7.4.25 Mosaicism

*Germline mosaicism* is a relatively frequent mechanism of inherited disease and provides an explanation for the inheritance pattern in cases where multiple affected offspring are born to clinically and phenotypically normal parents (572). It arises through the occurrence of a mutation de novo in a germline cell or one of its precursors during the early embryonic development of the parent. Since mitotic divisions predominate in both spermatogenesis and oogenesis, most germline mutations are

likely to be mitotic rather than meiotic in origin. *Somatic mosaicism* results from mutations occurring during mitotic cell divisions in the embryo with subsequent clonal expansion of the affected cells (573). The clinical effect of somatic mosaicism depends critically upon the developmental stage at which the mutation occurs. Thus, a mutation that occurs very early on in embryonic development is likely to affect many somatic tissues. By contrast, mutations occurring rather later may give rise to a phenotype that is confined to a single body region or even to a single organ. Somatic mosaicism arising at a very early embryonic stage can involve both somatic cells and germ cells. Such individuals (*gonosomal mosaics*) are at risk of having affected children. Recent data support the postulate that the frequency of mosaicism is increased in cancer predisposition syndromes characterized by high new mutation rates, suggestive of a direct relationship between the mutation rate in the soma and that in the germline (574).

#### 7.4.26 Human Mutation Rates

Recent studies have estimated the human mutation rate per nucleotide per generation to be between  $7.6 \times 10^{-9}$  and  $2.2 \times 10^{-8}$  (575,576). This equates to an average of 50–100 de novo mutations in a newborn genome, which corresponds to  $\sim 0.86$  de novo amino acid altering mutations. The genome-wide CNV mutation rate has also been estimated using SNP microarrays; at a resolution of  $\sim 30$  kb, Itsara et al. observed 9 de novo CNVs from 772 transmissions, corresponding to a mutation rate of  $1.2 \times 10^{-2}$  CNVs per genome per transmission (577).

Sex differences in mutation rates may have a variety of different underlying causes. For *premeiotic mutations*, the single most important factors are likely to be the much higher number of cell divisions during spermatogenesis as compared to oogenesis and the fact that the number of male germ cell divisions experienced is age dependent (578). However, the likelihood of a given mutation having originated in a particular parent is often dependent on the nature of the mutation in question. In general, point mutations tend to display a paternal bias, arising during spermatogenesis, while gross deletions tend to occur predominantly in females having originated during oogenesis (579,580). The ratio of the male to female nucleotide substitution mutation rates has been estimated to be around 6 (79) but may be as high as 20 (581), rather higher than expectation based on the ratio of the relative numbers of male versus female germline cell divisions, and consistent with most mutations being replication driven. Recently, the complete genomes from two parent-offspring trios have been sequenced to  $>22$ -fold mapped depth; a total of 49 and 35 germline de novo mutations were identified in two parent-offspring trios, respectively. In one family, 92% of the de novo mutations originated from the paternal germline, whereas the

equivalent figure from the other family was 36% of de novo mutations (582).

#### 7.4.27 Concepts of Dominance and Recessiveness in Relation to the Underlying Mutations

A genetic character is held to be *dominant*, if it is manifest in the heterozygous state and *recessive* if it is not. Thus, for a truly dominant condition, homozygotes should be clinically and phenotypically indistinguishable from heterozygotes (583). If this is not so, and the homozygote is more seriously affected, then the respective alleles may be regarded as *semidominant* (584).

In general, most recessive alleles are loss-of-function alleles and include gross gene deletions and rearrangements, frameshift mutations, nonsense mutations, and so on. By contrast, dominant alleles are often associated with gain of function, either due to dominant negative mutations (which interfere with and hence abrogate the function of the wild-type allele) or dominant positive mutations (which confer increased, constitutive, novel, or toxic activity on the mutant protein). Examples of dominant negative mutations are to be found in the *GH1* (585) and *KIT* (586) genes, while dominant positive mutations have been reported in the *PMP22* (587), *GNAS1* (588), *DMPK* (589), and *SERPINA1* (368) genes. It should be noted that loss-of-function mutations [e.g. *TERT* (590) and *RUNX2* (591)] can also be associated with dominantly inherited conditions in cases where a 50% reduction in the level of the protein product is sufficient to impede function.

For X-linked diseases, it is probably inappropriate to use the terms dominant and recessive since males are hemizygous and females often display variable expressivity of their heterozygous mutations due to skewed X-inactivation or clonal expansion (592).

#### 7.4.28 Genetic Architecture of Complex Diseases

The study of the genetic architecture of complex disease has revolved around the discussion of two apparently opposing models: the common disease–common variant (CD/CV) hypothesis and the multiple rare variant or common disease–rare variant (CD/RV) hypothesis (466). Since the CD/CV model conceptually underpinned the HapMap Project, GWAS that have employed HapMap data have tended to interrogate the association of common SNPs (MAF  $>5\%$ ) with complex diseases and traits. Initial GWAS data, therefore, strongly supported the involvement of common variants, especially common SNPs in complex phenotypes (468). However, such studies have succeeded in explaining only a small fraction of the heritability of complex phenotypes (593) and this “missing heritability” has tended to challenge the validity of the CD/CV hypothesis. Perhaps not surprisingly,

more recent data are revealing contributions from both common and rare variants to complex phenotypes. Thus, although common SNPs can explain a greater proportion of the heritability than was initially appreciated (594), support for a role for rare variants has also been accumulating from studies of rare SNPs (595,596) and rare CNVs (264,265). This suggests that the genetic architecture of complex phenotypes is likely to comprise both common and rare variants.

## 7.5 GENERAL PRINCIPLES OF GENOTYPE-PHENOTYPE CORRELATIONS

Given knowledge of a specific clinical phenotype, to what extent can the underlying causal genotype be inferred? Conversely, given knowledge of a specific genotype, to what extent is it possible to infer the likely clinical phenotypic consequences (in terms, for example, of the penetrance, age of onset, and severity of the disease)? The study of the genotype-phenotype relationship is essentially an exploration of the actual correspondence between the genotype and the phenotype where any particular genotype usually corresponds to multiple phenotypes whereas many different genotypes can often correspond to a given phenotype. Several general principles have emerged as a result of the intensive study of causative mutations in genetic disorders. The following discussion highlights some of these principles. The reader is encouraged to use the On-line Mendelian Inheritance in Man (OMIM) at <http://www3.ncbi.nlm.nih.gov/Omim> for further information or for specific genes and clinical phenotypes. It is likely that the phenotypic consequences of a given mutation will depend on other genetic variants present in the same gene or in the same genome (597). The review of Wolf (598) provides an excellent guide to the complex issues inherent in the study of the relationship between the mutant genotype and the clinical phenotype.

### 7.5.1 Mutations in the Same Gene May Be Responsible for More Than One Disorder

There are many examples to illustrate the principle that mutations in a single gene can cause different and distinct clinical phenotypes (“allelic heterogeneity”). Historically, the first example is that of the  $\beta$ -globin (*HBB*) gene on 11pter. Mutations of this gene cause  $\beta$ -thalassemia, sickle cell disease, and methemoglobinemia. The *L1CAM* gene on Xq28 has been shown to be mutated in hydrocephalus and stenosis of aqueduct of Sylvius, MASA syndrome (mental retardation, aphasia, shuffling gait, and adducted thumbs), and spastic paraplegia 1. The *COL1A2* gene on 7q21-q22 is involved in four different clinical forms of osteogenesis imperfecta (types II, III, IV, and atypical) as well as Ehlers-Danlos syndrome type VII B. The fibroblast growth factor receptor 2 (*FGFR2*) gene is mutated in three different craniosynostosis syndromes,

namely Pfeiffer, Crouzon, and Jackson-Weiss. The *COL2A1* gene is implicated in Stickler syndrome type 1, SED congenita, Kniest dysplasia, achondrogenesis-hypochondrogenesis type 2, precocious osteoarthritis, Wagner syndrome type 2, and SMED Strudwick type. In a survey of 1014 genes causing disorders in OMIM, 165 genes were associated with two disorders, 52 genes with three disorders, 24 genes with four disorders, and 19 genes with five or more disorders (69).

### 7.5.2 One Disorder May Be Caused by Mutations in More Than One Gene

There are a plethora of similar clinical phenotypes due to mutations in different genes. This observation, also known as “nonallelic” or “locus” heterogeneity, is well understood thanks to linkage analyses for genetic disorders and the search for mutations in different genes. Thus, tuberous sclerosis, a relatively common autosomal dominant disorder, is caused by lesions in at least two different loci: *TSC1* on 9q34 and *TSC2* on 16p13.3. Approximately 60% of TSC families show linkage to the *TSC2* locus and 40% to the *TSC1* locus. HNPCC has been associated with mutations in five different genes: *MLH1* on 3p, *MSH2* on 2p16, *PMS1* on 2q31-q33, *PMS2* on 7p22, and *MSH6* on 2p16. Retinitis pigmentosa has so far been associated with a total of 23 different genes and the list is still growing. We expect that disorders of complex or polygenic phenotypes, such as hypertension, atherosclerosis, diabetes, schizophrenia, and manic-depressive illness, will be associated with a considerable number of genes scattered throughout the genome.

### 7.5.3 One and the Same Mutation May Give Rise to Different Clinical Phenotypes (“Polypheny”)

The clinical phenotype does not only depend on the one mutation in the responsible gene; it can be modified by the action of any of the other ~25,000–30,000 genes in the genome (Wolf, 1997). The environment can also play an important role in the full development of the clinical phenotype. The classic sickle cell disease mutation in the  $\beta$ -globin (*HBB*) gene (Glu6Val) may be associated with severe or mild sickle cell disease. The amelioration of the severe clinical phenotype in this case can be attributed to the increased expression of  $\gamma$ -globin genes and the presence of high levels of HbF. The genomic environment of the  $\beta$ -globin gene cluster may, therefore, modify the severity of sickle cell disease as may genetic variation originating from other loci, for example, the  $\alpha$ -globin genes (103). Another example of this phenomenon has recently been provided by studies of certain craniosynostoses. Both Pfeiffer and Crouzon syndromes can be associated with the same C342Y or C342R mutations in the *FGFR2* gene.

The clinical phenotype associated with the D178N missense mutation in the prion protein (*PRNP*) gene is critically dependent on the presence of the Met or Val129 polymorphic allele to which it is coupled. When D178N lies in *cis* to the Met129 allele, fatal familial insomnia (FFI) results, whereas D178N coupled to the Val129 allele is associated with Creutzfeldt–Jakob disease (599). The Met/Val129 polymorphism also exerts an effect in *trans* through the normal allele since FFI is more severe and of longer duration in patients homozygous for either the Met or the Val allele.

One of the best examples of the contribution of the environment to the clinical phenotype of single gene disorders is that of phenylketonuria due to PAH deficiency. Individual homozygous or compound heterozygous for mutations in the *PAH* gene develop severe mental handicap if fed a normal diet. However, the cognitive status remains normal if these individuals are fed with a special, “phenylalanine-free” diet.

#### 7.5.4 Mutations in More Than One Gene May Be Required to Express a Given Clinical Phenotype (Digenic Inheritance; Triallelic Inheritance)

Digenic inheritance refers to clinical phenotypes caused by the co-inheritance of mutations in two unlinked genes. Thus, one form of retinitis pigmentosa is due to the co-inheritance of mutations in the *RDS* gene on 6p and the *ROM* gene on 11q (600). Individuals with either one or the other mutation do not suffer from the disease. In similar vein, digenic inheritance of mutations in the *MITF* and *TYR* genes has been reported as a cause of Waardenburg syndrome type 2 in conjunction with ocular albinism (601). This phenomenon may be common in polygenic disorders and in disorders with “low penetrance.”

Triallelic inheritance refers to clinical phenotypes, with apparent recessive mode of inheritance, caused by the co-inheritance of three mutant alleles, two in one gene and one in another gene. An example of triallelic inheritance is provided by the Bardet–Biedl syndrome. There are pedigrees in which affected individuals have two mutant alleles in the *BBS6* gene and one mutant allele in the *BBS2* gene. Other pedigrees have two mutant alleles in the *BBS2* gene and one mutant allele in *BBS6* (602). This type of inheritance indicates that some forms of BBS have a complex pattern of inheritance. As above, this phenomenon may be relevant in polygenic disorders and in disorders with “low penetrance.”

#### 7.5.5 Different Mutations in the Same Gene May Give Rise to Distinct Dominant and Recessive Forms of the Same Disease

vWF deficiency is a relatively common monogenic disease of blood coagulation. Many mutations have been studied

in the *VWF* gene on chromosome 12p. A proportion of mutations (usually deletions, nonsense codons, or frame-shift mutations) cause vWF deficiency with a recessive mode of inheritance; other mutations (mostly missense substitutions) are, however, associated with a dominant mode of inheritance of the vWF deficiency (603).

Although the majority of hitherto characterized growth hormone (*GH1*) gene lesions (including gross deletions and missense/nonsense mutations) that underlie familial short stature are inherited in autosomal recessive fashion, there is a group of intron 3 splicing mutations that are characterized by a dominant mode of inheritance (415). These lesions result in the in-frame skipping of exon 3 encoding 40 amino acids including a Cys residue. The dominant negative nature of this type of mutation is thought to be explicable in terms of the participation of the resulting free unpaired cysteine residue in an illegitimate intermolecular disulfide linkage leading to dimerization of the mutant molecule with a normal GH molecule and inhibition of GH secretion.

### 7.6 WHY STUDY MUTATION?

Although the sequencing of the human genome was finished some time ago, its annotation is still far from complete (604–606). Full exploitation of the emerging data, specifically in relation to understanding the etiology of inherited disease and disease predisposition, is however likely to be hampered by our ignorance of the basic processes underlying interindividual, interpopulation, and interspecies genetic diversity. At the population level, such an understanding is seen as essential for any meaningful interpretation of the prevalence/incidence patterns observed for diseases with a genetic basis. Within families, it is a prerequisite for being able to explain how interindividual variation arises and how variable phenotypic expression can be associated with identical gene lesions. Thus, for human genome sequence data to be useful in the context of molecular medicine, they must eventually be related to the genetic variation underlying human inherited disease. To this end, the meta-analysis of pathological germline mutations in human genes should facilitate

1. the assessment of the spectrum of known genetic variation underlying human inherited disease (4),
2. the identification of factors determining the propensity of DNA sequences to undergo germline mutation (150),
3. the optimization of mutational screening strategies (607),
4. improvements in our ability to predict the clinical phenotype from knowledge of the mutant genotype (8,374),
5. the identification of disease states that exhibit incomplete mutational spectra, prompting the search for, and detection of, novel gene lesions associated with different clinical phenotypes (608),

6. extrapolation toward the genetic basis of other, more complex traits and diseases (609),
7. improvements in our understanding of the biological function(s) of a given protein (373),
8. meaningful comparison between the mechanisms of mutagenesis underlying both inherited and somatic diseases (571),
9. studies of human genetic diseases in their evolutionary context (189).

Our genes have evolved slowly, probably via a myriad of meandering and circuitous pathways, escorted through the millennia of erratic environmental influences by the molding force of natural selection. Perhaps this hesitant evolutionary past accounts for present day genes containing, encoded within their nucleotide sequences, the potential seeds of their own destruction. How apt in this context is the poet's description of nature: "so careful of the type she seems, so careless of the single life" (Alfred Lord Tennyson, "In memoriam A.H.H.", 1850).

## ACKNOWLEDGMENTS

The authors wish to thank Professor Michael Krawczak (Institut für Medizinische Informatik und Statistik, Christian-Albrechts-Universität Kiel, Germany) for his contributions to earlier published versions of this chapter and Peter Stenson and Eddy Ball for their provision of HGMD data. Earlier versions of this chapter have been published in other textbooks.

### Biographies

**Stylianos E Antonarakis** is currently professor and Chairman of Genetic Medicine at the University of Geneva Medical School. He is a medical, molecular, human geneticist, physician–scientist, who studied extensively the relationship between genomic variation and phenotypic variation. He received his MD (1975) and DSc (1982) from the University of Athens Medical School, and after a specialization in pediatrics in the University Hospital, Athens Greece, he moved to Baltimore, Maryland to become a medical geneticist at the Johns Hopkins University School of Medicine with Haig H Kazazian and Victor McKusick (1980–1983). He joined the faculty of the Johns Hopkins University in 1983 and rose to full professor of pediatric genetics, biology, and medicine in 1990. In 1992, he moved to Geneva, Switzerland to chair Genetic Medicine in the University of Geneva. His research work and accomplishments include the understanding of the molecular bases of monogenic disorders and complex genetic disorders including the  $\beta$ -thalassemias, hemophilias, and trisomy 21. His laboratory participated in the human genome sequence and functional analysis, particularly on chromosome 21. He is an international expert on disorders of chromosome 21, cloning of genes for genetic disorders, development of diagnostic tests, genome structure and function, studies of the genome variability, and conserved noncoding sequences in human DNA. He has published extensively (more than 600 well-cited papers) in the scientific literature and is coeditor of the current edition of the classic textbook *Genetics in Medicine*; he is listed as one of the highly cited scientists by the ISI institute (more than 35,000 citations; h-index 94). He was the President of the European Society of Human Genetics (2001–2002), and member of the HUGO Council, foreign member of the Academy of Athens (2003), and member of EMBO (2006). He was the co-organizer of the European School of Genetic Medicine, and in the last 28 years taught in the Bar Harbor Genetics Course, Maine. He was awarded the Society of Pediatric Research Young Investigator Award (1984), International Jerome Lejeune Prize (2004), the European Society of Human Genetics Award (2005), and was elected to the Society of Scholars of the Johns Hopkins University (2006), and the American Academy of Physicians (2010). He was awarded the Commander of the Order of Phoenix medal from the Hellenic Democracy (2007). More than 70 talented young scientists were trained in his laboratory (graduate students and postdoctoral fellows); in addition, more than 25 young physicians were trained in the Medical Genetics Clinic of his department. With Haig Kazazian he has established one of the first molecular diagnostic laboratories in the United States as early as 1982. He is a member of the Swiss National Science Foundation Research Council, and the Chair of the Genetics Review Panel of the EU ERC. His research laboratory was/is supported by grants from the National Institutes of Health, the European Union (including the European Research Council), and the Swiss National Science Foundation and numerous other Foundations including the Gebert and Lejeune Foundations. He is the originator of the World Down Syndrome Day ([http://en.wikipedia.org/wiki/World\\_Down\\_Syndrome\\_Day](http://en.wikipedia.org/wiki/World_Down_Syndrome_Day)). His current interests and research projects are the functional analysis of the genome, effect of human genetic variation to phenotypic variation, the molecular pathogenesis of trisomy 21 and polygenic phenotypes, the functional characterization of the conserved fraction of the genome, diagnostics and prevention of genetic disorders, and the societal implications of genetics and genome research.

**David N Cooper** is professor of human molecular genetics at Cardiff University. He obtained his PhD in molecular biology from Edinburgh University in 1983. Having worked on the molecular genetics of inherited disorders of thrombosis and hemostasis at the University of London, he took up his present position in 1995. His research interests are largely focused on elucidating the mechanisms of mutagenesis underlying human genetic disease, but include the exploration of genotype–phenotype relationships in various inherited conditions, as well as human evolutionary and population genetics. He has published more than 340 papers in the field of human molecular genetics and has coauthored or coedited a number of books including *Human Gene Mutation* (1993), *Nature Encyclopedia of the Human Genome* (2003), *Molecular Genetics of Lung Cancer* (2005), *Handbook of Human Molecular Evolution* (2008), and *Copy Number Variation and Disease* (2009). He curates the *Human Gene Mutation Database* (<http://www.hgmd.org>), a comprehensive database of mutations causing human inherited disease, which is marketed internationally by BIOBASE GmbH. Professor Cooper is European editor of *Human Genetics* and editor of the Genetics and Disease section of Wiley's *Encyclopedia of Life Sciences*. He is also a member of several editorial boards including the *Journal of Medical Genetics* and *Human Mutation*.

## Genes in Families

*Jackie Cook*

Sheffield Regional Genetics Service, Sheffield Children's Hospital, Western Bank,  
Sheffield, South Yorkshire, UK

This article is a revision of the previous edition article by Jackie Cook, Wayne Lam and Robert F Mueller, volume 1, pp 129–143, © 2001, Elsevier Ltd.

### 8.1 INTRODUCTION

Genetic counseling is the process by which patients and relatives at risk of a disorder that may be hereditary are advised of the consequences of the disorder, the probability of developing and transmitting it, and of the ways in which this may be prevented, avoided, or ameliorated. To achieve these aims, an accurate diagnosis and detailed information regarding the family history are essential. The basis for establishing a diagnosis depends on medical history, examination, and investigation. The diagnostic information is combined with the information obtained from the family pedigree to determine the mode of inheritance of the disorder and to calculate the risk of recurrence so that family members can be appropriately counseled.

A family history of a genetic condition may be due to the following:

1. A mutation within a single nuclear gene
2. A mutation within a mitochondrial gene
3. A contiguous gene deletion or duplication involving anything from a few to a large number of genes
4. A chromosomal rearrangement resulting in unbalanced products at meiosis
5. Multifactorial inheritance

### 8.2 PEDIGREE CONSTRUCTION

Accurate documentation of the family history is an essential part of genetic assessment, and the best method of recording this information is by constructing a family pedigree. Pedigrees are universally used in patients' genetic records, journal articles, and textbooks as the means of relaying information in an easily interpreted visual format. Pedigrees also provide the basis for calculations required for both recurrence risk estimation in individual families and linkage analysis in gene-mapping studies.

In a pedigree, squares are used to represent males and circles to represent females. Generations are indicated

by Roman numerals and individuals within each generation by Arabic numbers. Despite the universal use of the pedigree as a method of recording information and as an analytical tool, there is still considerable variation in the use of symbols relating to both routine medical information (pregnancy, spontaneous abortion, and termination of pregnancy) and new reproductive technologies (artificial insemination by donor semen, donor ovum, and surrogate motherhood).

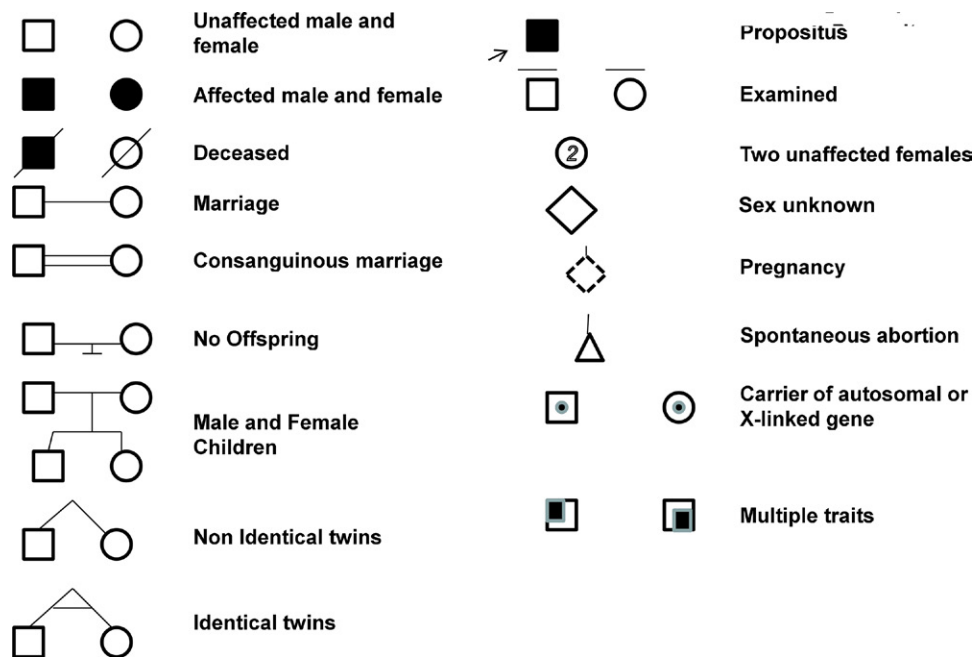

An example of a family pedigree is shown in [Figure 8-1](#), using the symbols illustrated in [Figure 8-2](#). While drawing a pedigree, it is usually simplest to start with the person seeking advice (the consultand). In some cases, the consultand will be an apparently healthy relative seeking information about how the condition may affect him/her or his/her offspring. Pedigree details are completed for both sides of the family, including previous and subsequent generations.

Conventionally, the paternal lineage is placed on the left and the maternal lineage on the right. Within sibships, individuals are listed from left to right in birth order. The affected person (proband), through whom the family has been ascertained, or the relative seeking advice (the consultand), are normally indicated in the pedigree by an arrow. Name, date of birth, and a summary of relevant medical details should be recorded for all family members. Further information, including medical records, may be required for affected individuals to confirm actual diagnosis. Not all relevant information may be volunteered by the consultand, indeed certain sensitive information—such as a previous termination of pregnancy or illegitimacy—may be deliberately withheld if the accompanying partner is not aware of it. Important details that should be asked about include assisted conception, previous miscarriages, stillbirths, terminations, children adopted into or out of the family, and consanguinity. Ethnic origin should be recorded, as

**FIGURE 8-1** Example of a family pedigree for Duchenne muscular dystrophy.

**FIGURE 8-2** Examples of symbols commonly used in drawing a pedigree.

some genetic conditions are more prevalent in particular ethnic groups, and this information may provide a clue to the likely diagnosis. The family history should be completed on both sides of the family for a consultant couple, even if the presenting condition is clearly traced to one side, as unrelated pregnancy losses or handicapping disorders may have occurred on the other side of the family that could have greater reproductive impact for the couple than the disorder for which they are seeking information.

### 8.3 UNIFACTORIAL INHERITANCE/ SINGLE-GENE DISORDERS

Unifactorial inheritance refers to those disorders that are due to the inheritance of a single mutant gene. The first descriptions of unifactorial inheritance were made by Mendel in 1865, when he published the results of his experiments on the garden pea in his paper “Versuche über Pflanzen Hybriden” (“Experiments on Plant

Hybrids”). His work was largely ignored until it was republished by Bateson in 1901, from which time the term Mendelian inheritance became synonymous with unifactorial inheritance.

From the ratios that Mendel described in his experiments on the garden pea, and the work of subsequent researchers, including Bateson, four main conclusions were drawn (1):

1. Genes come in pairs (Mendel termed them factors), one inherited from each parent.
2. Individual genes can have different alleles, some of which (dominant traits) exert their effects over others (recessive traits)—the principle of dominance. In Mendel’s own words, “those characters which are transmitted entire, or almost unchanged in the hybridization, and therefore in themselves constitute the characters of the hybrid, are termed the dominant, and those which become latent in the process, recessive.”

3. At meiosis, alleles segregate from each other with each gamete receiving only one allele—the principle of segregation, or Mendel's first law.
4. The segregation of different pairs of alleles is independent—the principle of independent assortment, or Mendel's second law.

With time, these principles have had to be modified. For example, although most genes come in pairs, for genes on the sex chromosomes males have only one allele; that is, they are termed hemizygous. Also, although alleles of a gene on different chromosomes show independent assortment, genes that are physically close together on the same chromosome do not—a phenomenon that has allowed mapping of genes in the human genome through linkage studies. These principles, however, still form a useful set of rules designed to explain the inheritance of many inherited characteristics and disorders.

Diseases inherited in a Mendelian fashion are categorized according to whether the gene is on an autosome or a sex chromosome and whether the trait is dominant or recessive.

## 8.4 DOMINANCE AND RECESSIVENESS

### 8.4.1 Definition of Dominance

Fundamental to the understanding of Mendelian inheritance are the concepts of dominance and recessiveness. Dominance is not a property intrinsic to a particular allele, but describes the relationship between it and the corresponding allele on the homologous chromosome. If the phenotypes associated with the genotypes AA and AB are the same but differ from the phenotype of BB, allele A is dominant to allele B and, conversely, allele B is recessive to allele A. Therefore, allele A manifests in the heterozygous state. An example of a dominant disease allele is that of Huntington disease, with most individuals affected with the disease being heterozygous for a mutant allele. However, individuals have been identified who have been shown by molecular techniques to be homozygous for the mutant allele by virtue of both parents being affected with Huntington disease. Such individuals do not appear different phenotypically from heterozygotes for the disorder.

**8.4.1.1 Incomplete Dominance.** If the phenotype of the heterozygous state, AB, is intermediate between the phenotypes of AA and BB, allele A is said to be incompletely dominant or semidominant to allele B. The skeletal dysplasia achondroplasia causes rhizomelic shortening of the limbs, a characteristic facies with mid-face hypoplasia, exaggerated lumbar lordosis, limitation of hip and elbow extension, genu varum, and trident hand. It was conventionally thought to be due to a dominant allele, but homozygotes for the mutant gene have a much more severe skeletal dysplasia, resulting in early

death from respiratory obstruction due to a small thoracic cage and neurologic deficit due to hydrocephalus. Therefore, achondroplasia is an example of incomplete or semidominance. Homozygotes for most dominant mutant alleles causing human genetic diseases occur so rarely that it is not known whether they exhibit complete or incomplete dominance.

**8.4.1.2 Codominance.** If the phenotype of AB displays the phenotypic features of both the homozygotic states, then alleles A and B are said to be codominant. The human ABO blood group system exhibits codominance. The system consists of three alleles: A, B, and O. Both A and B are dominant in relation to O, and therefore blood group A can have the genotype AA or AO. Blood group B can have the genotype BB or BO. However, neither A nor B shows dominance over the other, and therefore individuals with the genotype AB have the phenotypic characteristics of both blood group A and blood group B.

### 8.4.2 Mechanisms of Dominance

Most mutations result in an allele that is recessive to the wild-type allele; the phenotype is therefore only expressed in the homozygous state. This is because most mutations result in an inactive gene product, but the reduced level of activity due to the remaining wild-type allele is sufficient to achieve the effects of that gene product. An example is a gene for an enzyme that is only required in small amounts as a catalyst for a metabolic pathway. Although in some recessive inborn errors of metabolism it is possible to identify heterozygotes, more often than not, the only way to identify carriers is by direct mutation analysis, using molecular genetic techniques.

There are several mechanisms by which a mutation can lead to a dominant mutant allele whose phenotype is expressed in the heterozygous state (2).

**8.4.2.1 Loss-of-Function Mutations.** For most mutant alleles, loss of function will usually exhibit recessive behavior. Where a reduced amount or reduced activity of the gene product results in the phenotypic features, this is termed haploinsufficiency (e.g. in a critical rate-limiting step of a metabolic pathway). Any reduction in the amount of gene product will result in that pathway not being able to function at full activity. The same appears to apply to regulatory genes that could have a threshold level of activity. PAX3 is a gene coding for a DNA-binding protein, and point mutations in the gene result in Waardenburg syndrome type 1, characterized by deafness and pigmentary disturbances. Certain mutations in PAX3 have been shown to abolish all protein functions of that allele, so the phenotype must be due to a dosage effect as it manifests in the heterozygous state.

Another example in which the quantitative amount of a gene product is important is the genes that produce proteins in large quantities. An example is the gene for C1 esterase inhibitor, mutations of which cause the

disorder hereditary angioneurotic edema. C1 esterase inhibitor is removed rapidly from the circulation at a rate independent of its concentration. Therefore, although heterozygotes produce 50% of the normal amount, they have only 15–20% of the normal amount in the circulation, leading to the clinical manifestations of the disorder.

#### 8.4.2.2 Gain-of-Function Mutations.

**8.4.2.2.1 Increased Gene Dosage.** This mechanism involves an excess of gene product leading to a disease phenotype. Although gene dosage of critical regions or genes has been invoked as the cause for the phenotypic features associated with autosomal trisomies, there are a few examples involving single-gene disorders. One example involves the *PMP22* gene, which codes for the peripheral myelin protein 22. Duplication of the DNA sequence of one allele is associated with hereditary motor and sensory neuropathy type 1A.

**8.4.2.2.2 Ectopic or Temporally Altered Messenger RNA Expression.** Ectopic or temporally altered messenger RNA is expressed when a mutation occurs that affects the time or place of gene expression and usually involves a regulatory part of the gene. For example, during development in erythroid precursor cells, there is a switch from the production of  $\gamma$ -globin to the production of the  $\delta$ -globin and  $\beta$ -globin. This switch is controlled, at least in part, by the binding of transcription factors to the  $\gamma$ -globin promoter. Point mutations in the globin-promoter region prevent the normal switch, resulting in the disorder of hereditary persistence of fetal hemoglobin.

**8.4.2.2.3 Increased Protein Activity.** Mutations can lead to proteins with a prolonged half-life or proteins that have lost their normal constitutive inhibitory regulatory activity. If a mutation occurs in a part of a gene that codes for the protein sequence acting as the recognition site for proteolytic degradation, this will not take place, with the protein remaining active. Many proteins possess domains that allow their activity to be reversibly inhibited. For example, skeletal muscle sodium channels undergo voltage-sensitive regulation, and mutations in the gene *SCN4A* that codes for the  $\alpha$  subunit of the sodium channels result in the disorder hyperkalemic periodic paralysis, characterized by muscle myotonia and paralysis due to loss of regulatory inactivation of the sodium channel.

**8.4.2.2.4 Dominant-Negative Mutations.** If a mutant allele interferes with the wild-type allele, this is termed a dominant-negative mutation. This could occur in a multimeric protein in which a mutant subunit has an intact binding domain but altered catalytic activity, affecting the function of the entire multimer. If a protein is a dimer, one mutant and one wild-type allele would result in only 25% normal dimers, with up to a 75% reduction in activity.

Many structural proteins are multimers (e.g. the various types of collagen proteins). Each of the collagen

subunit genes has a central portion coding for repeating tripeptide units that are essential for the assembly of the collagen molecule. The disease *osteogenesis imperfecta* is caused by point mutations in the central portion of one of the collagen subunit genes *COL1A1* or *COL1A2* leading to a structural deformation that causes disruption of the whole collagen protein.

**8.4.2.2.5 Toxic Protein Alterations.** Toxic protein alterations are mutations that cause structural alterations in proteins, thus disrupting normal function and leading to toxic products that poison the cell. An example is hereditary amyloidosis, in which mutations in the transthyretin gene lead to resistance to proteolysis, and hence to increased stability of the protein. The protein then undergoes multimerization and accumulates in the cell as fibrils, causing disruption of the cell.

**8.4.2.2.6 New Protein Functions.** Some mutations have been found to confer a new function on a gene product. For example, a fatal bleeding disorder was found to be caused by a missense mutation in the  $\alpha_1$ -antitrypsin gene, in which methionine was replaced by arginine at position 358, the effect of which was to convert  $\alpha_1$ -antitrypsin, normally an inhibitor of elastase, into an inhibitor of thrombin. This thrombin inhibitory activity was not compensated for by an increase in endogenous coagulant production, resulting in a severe bleeding disorder (3).

**8.4.2.3 Recessive Mutations with Dominant Effects.** The mechanisms described so far show how mutations can cause dominant effects at a cellular level by the effects on the proteins produced. It is possible to have mutations that show a dominant pattern of inheritance in families, yet are recessive at the cellular or molecular level; that is, the gene is inactivated but has no other effect. The classic example of this is the retinoblastoma gene *RB1*, inactivation of which can lead to the formation of the developmental eye tumor retinoblastoma. Families can show a dominant mode of inheritance for this disorder, yet cells heterozygous for the mutation are completely normal, the mutation itself being recessive.

The dominant pattern of inheritance of familial retinoblastoma is the result of transmission of a first mutation with a second somatic mutation occurring in the normal allele of at least one retinal cell during a critical period of development, leading to the formation of a retinoblastoma—the “two-hit” hypothesis (4). There are several ways in which the normal allele in somatic cells can be inactivated. These include point mutations, deletions, translocations, and mitotic nondisjunction, resulting in the loss of a whole chromosome. It is now known that the two-hit hypothesis applies to most of the dominantly inherited familial cancer syndromes in which the germ line mutation in a tumor suppressor gene is recessive and a mutation in a somatic cell in the corresponding allele leads to the development of a tumor.

**TABLE 8-1** Characteristics of an Autosomal Dominant Inherited Disorder

Successive or multiple generations in a family are affected.
Males and females are both affected in approximately equal proportions.
Males and females can both be responsible for transmission.
There is at least one instance of male-to-male transmission.

**FIGURE 8-3** Pedigree consistent with autosomal-dominant inheritance.

## 8.5 AUTOSOMAL-DOMINANT INHERITANCE

Autosomal-dominant inheritance refers to disorders caused by genes located on the autosomes, thereby affecting both males and females. The disease or mutant alleles are dominant to the wild-type alleles, so the disorder is manifest in the heterozygote (i.e. an individual who possesses both the wild-type and the mutant allele). The necessary characteristics to be certain that a disorder is inherited in an autosomal-dominant manner are listed in Table 8-1 and depicted in Figure 8-3.

### 8.5.1 Recurrence Risks

Since individuals with autosomal-dominant disorders are heterozygous for a mutant and a normal allele, there is a 1-in-2 (50%) chance a gamete will carry the normal allele and a 1-in-2 (50%) chance a gamete will carry the mutant allele. Assuming that the individual's partner will contribute a normal allele, there is a 1-in-2 (50%) chance that the offspring, regardless of sex, will inherit the disorder with each pregnancy (Figure 8-4).

### 8.5.2 Penetrance

There can be marked variability in the clinical manifestations of autosomal-dominant disorders, and they can demonstrate reduced penetrance (i.e. not every person with the mutant allele shows features of the disorder). The penetrance of a disorder is an index of the proportion of individuals with a mutant allele who manifest the

**FIGURE 8-4** Recurrence risks in autosomal-dominant inheritance.

disorder. An allele is said to be nonpenetrant if an individual known to be heterozygous for the allele, either by pedigree analysis or by molecular investigation, shows no signs of the disorder when subjected to appropriate clinical investigation. The penetrance of some genes is dependent on the age of the individual, as in Huntington disease, in which the penetrance is age dependent or is said to show delayed penetrance.

The penetrance (P) of a disorder is usually expressed as a proportion or percentage of the individuals carrying the gene who develop the disorder. If the P value is known for a particular condition, the risk to the offspring of an apparently unaffected individual can be calculated. In practice, the risk is usually less than 10%, as an unaffected relative is not likely to carry the gene if the penetrance is high, and a gene carrier is not likely to develop the disorder if the penetrance is low.

### 8.5.3 Expressivity

The expressivity of a gene is the degree to which a particular phenotype is expressed in an individual. Many autosomal-dominant diseases show variable expressivity such that individuals in the same family who carry an identical mutation can vary considerably in the severity of their disorder. For example, in the autosomal-dominant disorder neurofibromatosis type 1, the number of neurofibromas that an individual develops can vary dramatically from a few to many hundreds even within the same family. The variability seen in autosomal-dominant disorders may present as both inter- and intrafamilial differences. Intrafamilial variability may reflect the action of modifying genes, but interfamilial variability is more likely to be due to allelic heterogeneity at a single locus. A problem encountered in genetic counseling is that a mildly affected individual, such as a parent with only skin manifestations of tuberous sclerosis, may have a severely affected child. This situation is seen in many autosomal-dominant disorders, in that the mildly affected individuals are more likely to reproduce than the severely affected individuals.

### 8.5.4 Anticipation

A disorder is said to demonstrate anticipation if the phenotype of the mutant allele increases in severity as it is passed down the generations. An example of a disorder that demonstrates anticipation is myotonic dystrophy. A typical three-generation family with myotonic dystrophy showing anticipation is shown in [Figure 8-5](#). Another example of anticipation is seen in Huntington disease, in which the onset of symptoms is often seen to occur earlier with each succeeding generation.

### 8.5.5 Sex Influence

Sex influence involves the expression of an autosomal allele that occurs more frequently in one sex than the other. An example in humans is gout, with males affected more frequently than females until after the menopause, an effect probably mediated by hormonal differences.

### 8.5.6 Sex Limitation

Some traits are manifested only in individuals of one sex, an extreme situation known as sex limitation. This can occur when a gene affects an organ only possessed by one of the sexes (e.g. unicornuate uterus or ovarian cancer).

### 8.5.7 Pleiotropy

Pleiotropy refers to the phenomenon in which a single gene is responsible for a number of distinct and seemingly unrelated phenotypic effects. For example, the allele causing neurofibromatosis type 1 can produce abnormalities of skin pigmentation, neurofibromas of the peripheral nerves, short stature, macrocephaly, skeletal abnormalities, and fits. Each of the pleiotropic effects

of an allele can show reduced or nonpenetrance and variable expressivity.

### 8.5.8 Mechanisms of Reduced Penetrance and Variable Expressivity

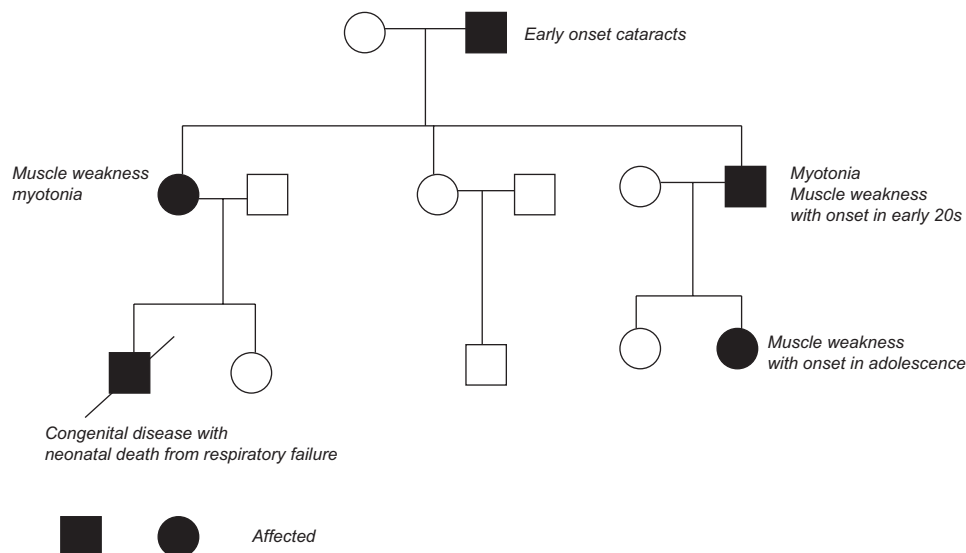

Some of the underlying mechanisms accounting for reduced penetrance and variable expressivity have been known for some time, while others are only now becoming apparent with the advent of modern molecular genetic techniques.

**8.5.8.1 Environmental Factors.** Environmental influences can affect the expression of genes. This can involve factors in the internal environment, such as hormones, or in the external environment, such as the effect of certain drugs and as barbiturates in acute intermittent porphyria. This disorder is characterized by attacks of abdominal pain, constipation, and psychiatric disturbances and is due to a mutation in a gene coding for an enzyme involved in heme biosynthesis. Attacks can be precipitated by certain drugs, including phenobarbital and the sulfonamides. Avoidance of these precipitating factors will result in nonpenetrance of the disorder.

**8.5.8.2 Somatic Mutations.** Retinoblastoma has already been mentioned as an example of one of the familial cancer genes in which a “second-hit” somatic mutation needs to occur in order for the disorder to manifest.

**8.5.8.3 Unstable DNA Triplet Repeat Sequences.** There are a group of dominant genetic disorders in which the mutation is an unstable DNA triplet repeat sequence that expands in successive meioses and whose size correlates with the severity of the disorder. This accounts for the anticipation seen in such disorders as myotonic dystrophy and Huntington disease.

**8.5.8.4 Genetic Background.** Information from studies of inbred animals suggests that it is likely that the genetic background of an individual (i.e. the nature of

**FIGURE 8-5** Pedigree for a family with myotonic dystrophy demonstrating anticipation.

particular alleles at other loci that interact with a mutant allele) will influence the penetrance and expression of a disorder. Analysis of the effect of this type of interaction is complex and is poorly understood at present, although examples are beginning to be delineated. For example, a study suggests that the alleles of the SMAD3 gene, which encodes a key regulatory protein in the transforming growth factor beta signaling pathway and is known to interact indirectly with the breast/ovarian cancer gene BRCA2 may contribute to an increased risk of breast cancer in BRCA2 mutation carriers (5).

### 8.5.9 New Dominant Mutations

While nonpenetrance can be a possible cause of a dominant disorder arising in the offspring of completely normal parents, an alternative explanation is that a mutation has arisen during the transmission of the gene; that is, it represents a new or *de novo* mutation. This appears to be more common for certain disorders than others. For example, in achondroplasia both parents are of normal stature in 80% of families. This also reflects the reduced reproductive fitness of adults with achondroplasia. The observation that achondroplasia occurred more frequently in last-born children of a sibship was suggested by Penrose as attributable to increased paternal age associated with new mutations, on the basis that “older germ-cells, possessed by older parents, might be more likely to show deterioration in the form of genetical changes” (6).

Some dominant mutations are universally lethal before the affected individual reaches reproductive age, and therefore are always seen as new dominant mutations. Several lethal disorders that were previously considered to be recessive are now known in many instances to be due to new dominant mutations, such as the perinatal lethal form (type II) of *osteogenesis imperfecta*.

New dominant mutations that occur during gametogenesis are associated with a negligible recurrence risk for future siblings. However, if the disorder is compatible with survival to reproductive age (and the possibility of reproduction), the recurrence risk for the offspring of the affected individual is 50%.

### 8.5.10 Gonadal or Somatic Mosaicism

In the case of certain new dominant mutations, there is a small but significant risk that a second child will be affected despite both parents being clinically normal. The ability to determine the molecular basis of many of these disorders has shown that this finding can be explained by the phenomenon of somatic mosaicism. This is possible when there are two genetically different types of cell in an individual, one carrying the mutant allele and the other not. If two genetically different types of cells occur within the gonads, this is referred to as gonadal mosaicism. However, there may be no mosaicism present in the gonads, where all cells may carry the mutant gene,

and the mosaicism may be present in other tissues. This situation would more correctly be referred to as somatic mosaicism.

The mutational event occurs after fertilization, with the degree and tissue specificity of the mosaicism being dependent on the time when it occurred. There is evidence that this usually occurs early in development, as commitment of primordial cells to the germ line occurs before tissue allocation, and in studies of individuals with gonadal mosaicism, up to 50% also have the mutation in a somatic cell line.

The frequency of gonadal mosaicism differs between disorders. At present, it is unclear why it is a frequent finding; however, it is now known that genetic heterogeneity with several newly discovered auto-recessive forms of IO can account for a good deal of the increased risks to unaffected parents. In some disorders such as fascioscapulohumeral dystrophy and osteogenesis imperfecta, mosaicism is found in approximately 19% and 15% of all cases, respectively (7), while in others such as achondroplasia, there have only been a few rare case reports. This is an important point to remember while providing recurrence risk advice in genetic counseling.

Somatic mosaicism may also be present in an individual who manifests the phenotype of an autosomal-dominant disorder. A study looking at individuals who were the first members of their families to develop the signs of neurofibromatosis type 2, a disorder characterized by bilateral vestibular schwannomas, estimated that 24.8% of their study cohort were mosaic for the NF2 mutation (8). Therefore, a new dominant mutation may arise during meiosis as a germ line mutation or postconceptually as a somatic mutation that is then transmitted through the germ line.

## 8.6 AUTOSOMAL RECESSIVE INHERITANCE

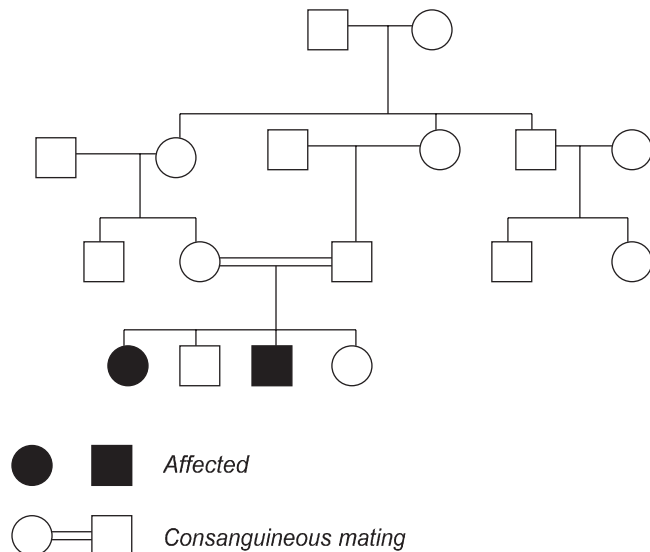

Autosomal recessive inheritance refers to disorders due to genes located on the autosomes, but in which the disease alleles are recessive to the wild-type alleles and are therefore not evident in the heterozygous state, only being manifest in the homozygous state. The necessary characteristics to be certain that a disorder is inherited in an autosomal recessive manner are listed in Table 8-2 and depicted in Figure 8-6. The parents of an individual with an autosomal recessive disorder are heterozygous for the disease allele and are usually referred to as being carriers for the disorder.

### 8.6.1 Consanguinity

If a couple are consanguineous, they have at least one ancestor in common in the preceding few generations. This means that they are more likely to carry identical alleles inherited from this common ancestor and could both transmit an identical allele to their offspring, who

**TABLE 8-2** Characteristics of an Autosomal Recessive Inherited Disorder

Both males and females are affected.
The disorder normally occurs in only one generation, usually within a single sibship.
The parents can be consanguineous.

**FIGURE 8-6** Pedigree consistent with autosomal recessive inheritance.

would then be homozygous for that allele. A consanguineous couple have an increased risk that their offspring will be affected with a recessive disorder. The rarer a particular disease is in a population, the more likely the parents are to be consanguineous. For example, cystic fibrosis is a common autosomal recessive disorder in whites in Western Europe, with an incidence of ~1 in 2000. The incidence of consanguinity in the parents of children with cystic fibrosis is not appreciably greater than that in the general population. By contrast, with very rare autosomal recessive disorders such as alkaptonuria, eight of the first 19 families originally described by Garrod were consanguineous (9).

### 8.6.2 Recurrence Risks

When two parents carrying the same disease allele reproduce, there is an equal chance that gametes will contain the disease or the wild-type allele. There are four possible combinations of these gametes, resulting in a 1-in-4 (25%) chance of having a homozygous affected offspring, a 1-in-2 (50%) chance of having a heterozygous unaffected carrier offspring, and a 1-in-4 (25%) chance of having a homozygous unaffected offspring (Figure 8-7).

When an individual with an autosomal recessive disorder has children, they will only produce gametes

**FIGURE 8-7** Recurrence risks in autosomal recessive inheritance.**FIGURE 8-8** Recurrence risks for an individual with an autosomal recessive disorder and a normal partner.

containing the disease allele. Since it is most likely that their partners will be homozygous for the wild-type allele, the partners will always contribute a normal allele and therefore all the children will be heterozygous carriers and unaffected (Figure 8-8). If, however, an affected individual has children with a partner who happens to be heterozygous for the disease allele, there will be a 50% chance of transmitting the disorder, depending on whether the partner contributes a disease or a wild-type allele (Figure 8-9). Such a pedigree is said to exhibit pseudodominance (Figure 8-10).

In autosomal recessive disorders, the difficulty lies not with risk estimation, but in determining the underlying mode of inheritance, as these disorders usually present as isolated cases with little contributory information to be gleaned from the pedigree. Carrier risks to other relatives can be calculated from the pedigree, and carrier testing may be appropriate for disorders with a high gene frequency or when consanguineous marriages are planned. The risk to members of the extended family for having an affected child will depend on their own risk calculated from pedigree data and the population-based carrier risk

**FIGURE 8-9** Recurrence risks for an individual with an autosomal recessive disorder and a carrier partner.

**FIGURE 8-10** Pedigree of an autosomal recessive disorder showing pseudodominance.

appropriate to their spouse. Higher risks in consanguineous marriages are dependent on the degree of relationship between the partners. In disorders of unknown genetic etiology, consanguinity suggests, but does not prove, an autosomal recessive mode of inheritance.

### 8.6.3 Genetic Heterogeneity

It is not unusual in some recessive disorders, such as sensorineural deafness, for two affected individuals to have children. Assortative mating occurs in such instances because of social circumstances in which individuals with the same disability, such as deafness or visual impairment, are often educated together or share the same social facilities. If their disorder was due to a mutation in the same autosomal recessive gene, all their offspring would be affected. In a number of studies involving the offspring of parents with inherited sensorineural deafness, however, a significant proportion of such matings led to offspring with normal hearing. Although in some instances this could be due to other causes (e.g. acquired

causes being mistaken for inherited deafness), in most instances, the gene causing the deafness in the two parents is different, a phenomenon known as genetic heterogeneity. Each parent will transmit the mutant allele for their own deafness, but a wild-type allele of the gene involved in their partner's deafness. Therefore, the child is heterozygous for the two mutant alleles, what is known as a double heterozygote. This type of genetic heterogeneity involving different genes is known as locus heterogeneity.

Different modes of inheritance have also been documented for a number of clinically defined disorders with similar phenotypes. For example, autosomal dominant, autosomal recessive, and X-linked recessive inheritance have all been documented in hereditary spastic paraplegia, hereditary motor and sensory neuropathy, and retinitis pigmentosa depending on the causative gene. Locus heterogeneity makes it difficult to determine risks of recurrence for phenotypes that follow both dominant and recessive inheritance if the mode of inheritance is not clearly defined by the family pedigree. Laboratory analysis of families is also complicated by locus heterogeneity, as direct mutation analysis may not be practical for conditions in which one of the several/many genes is implicated and the suggestion of linkage between a polymorphic marker and the disease in a small family does not necessarily prove that a mutation at that particular locus is responsible.

Heterogeneity can also exist at the same locus; thus, an individual affected with a recessively inherited disorder can have two different mutations in the two alleles of the gene and is often called a compound heterozygote. Most individuals with recessive disorders are compound heterozygotes unless a specific mutation is especially prevalent in a particular population or the affected individual is the offspring of a consanguineous relationship, in which case the allele is likely to be identical by descent. This is known as allelic or mutational heterogeneity. The specific mutations that an affected individual possesses can, in fact, determine the severity of the disorder, as in cystic fibrosis, in which individuals who are homozygous for the most common mutation in the cystic fibrosis gene,  $\Delta F508$ , have a higher incidence of pancreatic insufficiency. As the underlying mutations causing disease are identified, it is becoming increasingly apparent that in many cases the exact nature of the mutation will determine the phenotype—a phenomenon known as genotype–phenotype correlation.

In some cases, different classes of mutations in a particular gene may act in a dominant or in a recessive manner. For example, a wide variety of phenotypes have been associated with mutations in the LaminA/C gene (10). These include mutations acting in an autosomal-dominant fashion, causing Emery–Dreifuss muscular dystrophy, limb girdle muscular dystrophy type 1B, dilated cardiomyopathy, familial partial lipodystrophy, and Hutchinson–Gilford progeria syndrome, as well as

mutations acting in an autosomal recessive fashion, such as Emery–Dreifuss muscular dystrophy, type 2B1 axonal neuropathy, and mandibuloacral dysplasia.

### 8.6.4 Uniparental Disomy

Uniparental disomy (UPD) refers to the presence of both homologs of a chromosome pair or chromosomal region in a diploid offspring being derived from a single parent. If the two homologs are identical due to an error in meiosis II, this is known as uniparental isodisomy, while if the two homologs are different but still from the same parent due to a meiosis I error, this is known as uniparental heterodisomy. UPD has been reported as a rare cause of the autosomal recessive disorder cystic fibrosis in the offspring of a couple in whom only one parent was a heterozygote carrier of the mutant allele. The affected offspring received both chromosome 7 homologs with the mutant allele from that parent. The recurrence risk in this situation would be negligible.

### 8.6.5 New Mutations

An autosomal recessive disorder may potentially be due to the inheritance of a mutation from one parent, with a *de novo* mutation occurring at the same locus on the chromosome inherited from the other parent. This is likely to be a very rare phenomenon, but accounts for some cases of spinal muscular atrophy due to a predisposition to generate deletions in the 5q13 region involving the SMN1 gene (11). The recurrence risk in this situation would relate to the risk of repeated *de novo* mutation and therefore negligible.

## 8.7 SEX-LINKED INHERITANCE

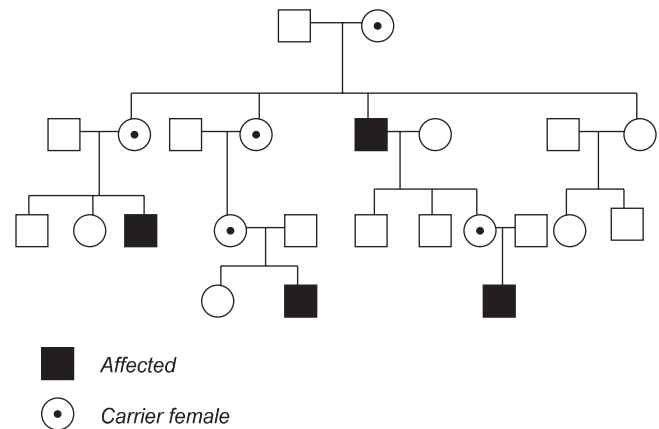

Strictly speaking, sex-linked inheritance refers to the inheritance patterns shown by genes on the sex chromosomes. If the gene is on the X chromosome, it is said to show X-linked inheritance and, if on the Y chromosome, Y-linked or holandric inheritance.

### 8.8 X-LINKED RECESSIVE INHERITANCE

This form of inheritance is conventionally referred to as sex-linked inheritance. It refers to disorders due to recessive genes on the X chromosome. Males have a single X chromosome and are therefore hemizygous for most of the alleles on the X chromosome so that, if they have a mutant allele, they will manifest the disorder. Females, on the other hand, will usually only manifest the disorder if they are homozygous for the disease allele, and if heterozygous will usually be unaffected. Since it is rare for females to be homozygous for a mutant allele, X-linked recessive disorders usually affect males only.

**TABLE 8-3** Characteristics of an X-linked Recessive Inherited Disorder

Males are affected almost exclusively.
Transmission occurs through unaffected or carrier females to their sons.
Male-to-male transmission is not observed.
Affected males are at risk of transmitting the disorder to their grandsons through their obligate carrier daughters.

**FIGURE 8-11** Pedigree consistent with X-linked recessive inheritance.

The necessary characteristics to be certain that a disorder is inherited in an X-linked recessive manner are listed in Table 8-3 and portrayed in Figure 8-11.

### 8.8.1 Recurrence Risks

If a male affected with an X-linked recessive disorder survives to reproduce, he will always transmit his X chromosome with the mutant allele to his daughters, who will be obligate carriers. An affected male will always transmit his Y chromosome to a son, and therefore none of his sons will be affected (Figure 8-12). A carrier female has one X chromosome with the wild-type allele and one X chromosome with the disease allele; therefore, her sons have a 1-in-2 (50%) chance of being affected, while her daughters have a 1-in-2 (50%) chance of being carriers (Figure 8-13).

For a female to be affected with an X-linked recessive disorder, her mother would have to be a carrier and her father affected with the disorder. Obviously, this situation is encountered only very rarely. Another possibility is that her mother is a carrier and the X chromosome transmitted by her father undergoes a new mutation. A female can also be affected by an X-linked recessive disorder if she has a single X chromosome (i.e. Turner syndrome), in which case she will be hemizygous for alleles on the X chromosome, like a male.

**FIGURE 8-12** Recurrence risks for a male with an X-linked recessive disorder.

**FIGURE 8-13** Recurrence risks for a female carrier of an X-linked recessive disorder.

## 8.8.2 X-Inactivation

Early in embryonic development, one of the X chromosomes in females is inactivated in each cell with the result that the female, like the male, has a single functional X chromosome. In individuals with X chromosome aneuploidies, all but one of the X chromosomes are inactivated in each cell. The process of X-inactivation is controlled by a region of the X chromosome, the X-inactivation center, situated on the proximal portion of the long arm. X-inactivation usually occurs as a random process such that, in approximately 50% of cells in a female, the maternally derived X chromosome is active, and in the other 50%, the paternally derived X chromosome is active. In females who are carriers of an X-linked recessive mutation, one half of the cells will actively express the disease allele. Occasionally, this can be demonstrated clinically. In X-linked *retinitis pigmentosa*, for example, careful fundoscopic examination of a female carrier can show a mosaic pattern of pigmentation.

## 8.8.3 Manifesting Female Carriers of X-Linked Recessive Disorders

Although female carriers of X-linked recessive disorders are usually asymptomatic, they can manifest signs of the disorder. They are usually much less severely affected than males, however. There are a number of different mechanisms by which a female heterozygote can manifest signs of an X-linked recessive disorder, but the underlying cause for each one is nonrandom or skewed X-inactivation. In this situation, there is a departure from the normal random process of X-inactivation, with a greater proportion of one X chromosome being inactivated than the other. If in most cells the active X chromosome is the one with the mutant allele, a female may manifest the disorder.

### 8.8.3.1 Mechanisms of Nonrandom X-Inactivation.

A number of mechanisms can lead to nonrandom X-inactivation:

1. *Chance*: Skewed X-inactivation can occur by chance.
2. *Monozygotic twinning*: There have been several reports of monozygotic female twins, both heterozygous for a dystrophin gene deletion, one of whom was a manifesting carrier for Duchenne-type muscular dystrophy and the other an unaffected carrier. It was demonstrated that, in lymphocytes and fibroblasts of the affected twin, the majority of active X chromosomes had the deletion, while in the unaffected twin, most active X chromosomes possessed the intact gene. It has been postulated that the twinning process could have been a consequence of cell surface differences as a result of X chromosome inactivation, leading to the separation of the two cell masses (12).
3. *Cytogenetic abnormalities*: In females with an X-autosome translocation, the normal X chromosome will be preferentially inactivated, maintaining the diploid state for the autosome involved in the translocation. If the translocation disrupts or interferes with the expression of a gene on the X chromosome, or if the X chromosome involved in the translocation carries a disease allele, that female will manifest the disorder. The finding of X-autosome translocations in manifesting female carriers of Duchenne-type muscular dystrophy was instrumental in the mapping and cloning of the dystrophin gene.
4. *Elimination of cells expressing the mutant allele*: If a gene on the X chromosome is required for cell survival, the normal gene will always be found on the active X chromosome and the defective gene on the inactive X chromosome in the mature cell population, even though X-inactivation occurred as a random process. This has been demonstrated in a number of disorders, including X-linked severe combined immunodeficiency, and can be used in the determination of carrier status for females at risk.

### 8.8.4 Gonadal Mosaicism

As with autosomal-dominant disorders, gonadal mosaicism is an important phenomenon in X-linked recessive disorders, occurring particularly frequently in Duchenne-type muscular dystrophy, in which it has been shown to occur in both male and female gametogenesis. It is important to take this into account when advising mothers of apparently sporadically affected males with Duchenne-type muscular dystrophy of recurrence risks.

Mutations arising during meiosis may occur in male or female germ-cells. If a particular mutation arises largely in male germ-cells, as in Lesch–Nyhan syndrome (13) and hemophilia A (14), the majority of mothers of affected boys will be carriers, and risks to sisters will be 50% regardless of how many unaffected brothers they have. In Duchenne muscular dystrophy, the overall mutation rate appears to be equal in males and females, but it has been suggested that most point mutations occur in spermatogenesis, while most deletions arise in oogenesis (15). In isolated cases, the recurrence risk might therefore be higher in nondeletion cases, as these mothers would be more likely to be carriers.

## 8.9 X-LINKED DOMINANT INHERITANCE

X-linked dominant inheritance is an uncommon form of inheritance and is caused by dominant disease alleles on the X chromosome. The disorder will manifest in both hemizygous males and heterozygous females. Random X-inactivation usually means that the females are less likely to be severely affected than hemizygous males, unless they are homozygous for the disease allele. The characteristics of an X-linked dominant inherited disorder are listed in Table 8-4 and depicted in Figure 8-14.

### 8.9.1 Recurrence Risks

Offspring of either sex have a 1-in-2 (50%) chance of inheriting the disorder from affected females (Figure 8-15). The situation is different for males affected by X-linked dominant disorders, whose daughters will always inherit the gene and whose sons cannot inherit the gene (Figure 8-16). An example of an X-linked dominant disorder is vitamin D-resistant rickets. X-inactivation

**TABLE 8-4** Characteristics of an X-linked Dominant Inherited Disorder

Daughters of affected males always inherit the disorder.
Sons of affected males never inherit the disorder.
Affected females can transmit the disorder to offspring of both sexes.
An excess of affected females exists in pedigrees for the disorder.

results in females with this disorder having less severe skeletal changes than those that occur in affected males.

An exception to the rule that females are less severely affected than males is craniofrontonasal dysplasia, in which heterozygous females have a coronal craniosynostosis and affected hemizygous males do not have a craniosynostosis. The condition is caused by mutations in the ephrin B1 gene, and it has been proposed that, in heterozygous females, patchwork loss of ephrin B1 disturbs tissue boundary formation at the developing coronal suture, whereas in males deficient in ephrin B1, an alternative mechanism maintains the normal boundary (16).

### 8.9.2 X-Linked Dominant Lethal Alleles

In some disorders due to mutant alleles of genes on the X chromosome, affected males are never or very rarely seen (e.g. incontinentia pigmenti and Goltz syndrome). This is thought to be due to a lethal effect of the mutant disease allele in the hemizygous male, resulting in nonviability of the conceptus during early embryonic development. As a consequence, if an affected female were to have children, one would expect a sex ratio of 2:1, female to male,

**FIGURE 8-14** Pedigree consistent with X-linked dominant inheritance.

**FIGURE 8-15** Recurrence risks for a female affected with an X-linked dominant disorder.

**FIGURE 8-16** Recurrence risks for a male affected with an X-linked dominant disorder.

**FIGURE 8-17** Recurrence risks for a female affected with an X-linked dominant disorder lethal in males.

in the offspring and that one half of the females would be affected, while none of the male offspring would be affected (Figure 8-17). The majority of the mothers of females with these X-linked dominant lethal disorders are generally unaffected, and the disease alleles are therefore thought to arise as new mutations.

Rett syndrome is an X-linked dominant condition caused by mutations in the MECP2 gene. Girls with classical Rett syndrome have severe mental retardation developing after a period of relatively normal development. The mutations that cause classical Rett syndrome are lethal in males; however, other mutations in the gene can give a pattern of mental retardation in males that behaves as an X-linked recessive condition—another example of genotype–phenotype correlation.

## 8.10 Y-LINKED (HOLANDRIC) INHERITANCE

Y-linked, or holandric, inheritance refers to genes carried on the Y chromosome. They therefore will be present only in males, and the disorder would be passed on to all

**FIGURE 8-18** Pedigree consistent with Y-linked inheritance.

**FIGURE 8-19** Recurrence risks for a male affected with a Y-linked disorder.

their sons but never their daughters (Figure 8-18). Genes involved in spermatogenesis have been mapped to the Y chromosome, but a male with a mutation in a Y-linked gene involved in spermatogenesis would probably be infertile or hypofertile, making it difficult to demonstrate (Figure 8-19) Y-linked inheritance. This situation may well change with the use of techniques such as intracytoplasmic sperm injection (ICSI) to treat male infertility, which will result in the transmission of the infertility to male offspring.

## 8.11 PARTIAL SEX LINKAGE

A small region of sequence identity exists between the X and Y chromosomes located at the tips of the long and short arms, known as the pseudoautosomal regions of the sex chromosomes. A high rate of recombination at the telomeres of the short arms is thought to be obligatory for normal meiosis of these chromosomes. The genes within these regions, known as pseudoautosomal genes, escape X-inactivation in the female; therefore, both sexes have two active alleles at these loci. The pseudoautosomal gene SHOX has been postulated to account for some of the features seen in the numerical sex chromosome disorder, Turner syndrome. As a

result of the high recombination frequency, mutated genes located within the pseudoautosomal region can be transferred from the Y chromosome to the X chromosome and vice versa. Haploinsufficiency of the SHOX gene is the cause of Leri–Weill dyschondrosteosis, and in one study about half of the segregations investigated showed a transfer of the SHOX abnormality to the alternate sex chromosome. Therefore, the condition can be inherited as either an X-linked dominant condition or, more rarely, a Y-linked condition. Affected men can transmit the mutation or deletion to a son as well as to a daughter (17).

### 8.11.1 Genomic Imprinting and Epigenetic Mechanisms

Genomic imprinting is a phenomenon in which gene expression depends on parental origin. Imprinting is due to an epigenetic mechanism, in which the primary DNA sequence of the gene is not changed, but transcriptional regulation is affected by mechanisms such as DNA methylation, histone acetylation, and histone methylation. In contrast to the biallelic expression of most genes, imprinted genes demonstrate monoallelic expression. This process modifies the transmission and expression of certain genetic diseases and should be borne in mind as a possible mechanism underlying disorders that do not follow typical Mendelian inheritance. Many disorders due to defects affecting imprinted genes arise *de novo*, but they can also be familial. For example, the familial paraganglioma syndrome is due to mutations in the succinate dehydrogenase subunits B, C, and D. SDHD is an imprinted gene with the paternal allele active in each cell and the maternal allele inactive. The mutation is dominant and an affected parent (male or female) has a 1-in-2 chance of passing it on to each child, but the child is at increased risk to develop paragangliomas if only the mutation is inherited from the father (Figure 8-20). Conversely, the Angelman's gene

UBE3A is imprinted in the opposite way so that only the maternal allele is active.

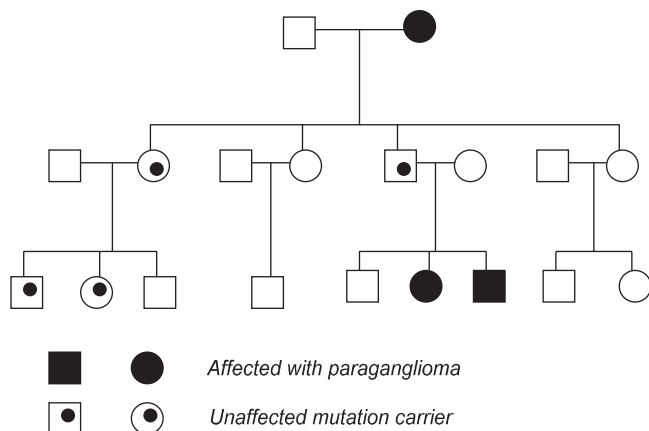

Prader–Willi syndrome (PWS) and Angelman syndrome are probably the best known examples of disorders due to imprinted genes. These disorders affect different genes in the imprinted region at 15q11-13. Loss of expression of paternal candidate genes in this region leads to PWS, and the loss of expression of the maternal UBE3A (ubiquitin protein ligase E3A) gene leads to Angelman syndrome. The underlying mechanism is often a *de novo* deletion or point mutation within the imprinted gene itself, but some cases are due to epigenetic mechanisms such as UPD or the consequence of an imprinting center defect. Maternal UPD results in PWS and paternal UPD in Angelman syndrome. Some familial cases of Angelman syndrome are due to mutations in the gene UBE3A. A mutation inherited from a mother will cause Angelman syndrome, but when inherited from the father the condition will not manifest. The imprint is reset during male and female gametogenesis. Therefore, in familial Angelman's, if an unaffected female carries a mutation in UBE3A on her paternal allele it is reset at gametogenesis so that it is now on the active allele and the children who inherit it will have Angelman syndrome.

Some genes show tissue-specific imprinting; for example, the GNAS gene, which causes Albright hereditary osteodystrophy (AHO). AHO is due to G(s)α inactivating mutations, imprinted in a tissue-specific manner, with expression in the proximal renal tubules, thyroid, pituitary, and ovaries being from the maternal allele. Maternally inherited mutations lead to AHO with endocrine involvement (pseudohypoparathyroidism type 1A), whereas paternally inherited mutations lead to AHO alone. Pseudohypoparathyroidism type 1B (parathormone resistance without AHO) can be caused by a deletion of the imprinted promoter regions of the gene that control gene expression (18).

An increased incidence of imprinted disorders, notably Beckwith–Wiedemann Syndrome, has been reported in children conceived by in vitro fertilization or ICSI techniques, suggesting that the process of resetting the parental imprint may be perturbed by specific elements of assisted reproductive methodology (19).

**8.11.1.1 Digenic Inheritance.** Genetic or locus heterogeneity by which different genes can cause clinically identical disorders has been discussed previously in this chapter. However, these cases are considered to be monogenic in that, in any one family, only one locus is thought to be defective. Reports of families with *retinitis pigmentosa* in which the affected individuals are heterozygous for mutations in two different recessive genes (i.e. double heterozygotes) suggested the possibility of a previously undescribed mode of inheritance, known as digenic inheritance (20).

Although the families described were initially thought to be compatible with autosomal dominant *retinitis*

**FIGURE 8-20** Pedigree showing familial paragangliomas and the effects of imprinting of the SDHD gene.

*pigmentosa* with reduced penetrance, the families showed a number of unusual features:

1. In each family, the disease originated in the offspring of unaffected individuals.
2. Affected individuals transmitted the disorder statistically significantly to fewer than 50% of their offspring.

On molecular testing, it was found that both the affected and the unaffected individuals carried a mutation in the *peripherin/RDS* gene. Affected individuals were also heterozygous for a mutation in the *ROM1* gene. These genes encode two of the polypeptide subunits of an oligomeric transmembrane protein complex present at the photoreceptor outer segment disc rims. Mutant *peripherin/RDS* protein can assemble with wild-type *ROM1* to form structurally normal complexes, but cannot assemble with mutant *ROM1* protein. Therefore, only the combination of the two heterozygous mutations is pathogenic (21).

Digenic inheritance has also been suggested in inherited sensorineural deafness and in arrhythmogenic right ventricular cardiomyopathy (22). Whether this is a true phenomenon and how common it is still to be fully elucidated.

**8.11.1.2 Triallelic Inheritance.** Bardet–Biedl syndrome (BBS) is a multisystem disorder characterized by obesity, retinal degeneration, polydactyly, gonadal, and renal malformations, and behavioral and developmental problems, with a population incidence of 1 in 14,000 to 1 in 16,000. Initially, segregation studies suggested that the inheritance pattern was autosomal recessive. BBS is a genetically heterogeneous condition and so far 14 genes have been identified accounting for about 70% of cases. BBS families demonstrate great intra- and interfamilial variation in the phenotype. A more complex inheritance pattern has emerged with the report that about 5% of cases have three mutations, two in one BBS gene, and a third in another BBS gene. There are a number of possible explanations for this finding. One is triallelic inheritance with the third allele affecting the variability in the phenotype that is seen in BBS. Alternatively, the third allele may represent a heterozygous recessive mutation which has no effect on the phenotype or a rare polymorphism (23).

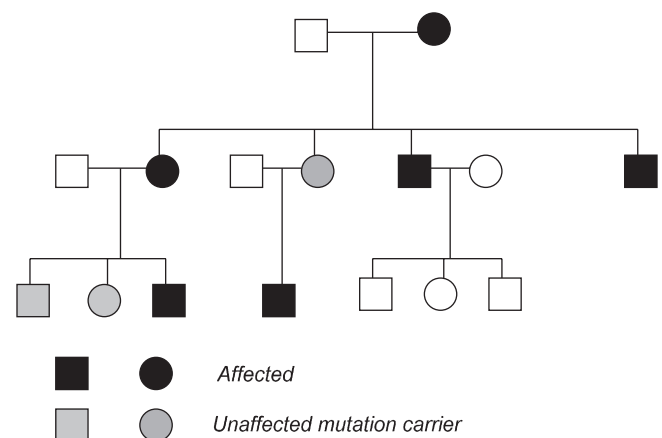

### 8.11.2 Mitochondrial Inheritance

The nuclear chromosomes are not the only source of coding DNA sequences within the cell. Mitochondria possess their own DNA, which, as well as coding for mitochondrial transfer RNA and ribosomal RNA, also carries the genes for 12 structural proteins that are all mitochondrial enzyme subunits. Mutations within these genes have been shown to cause disease (e.g. Leber's hereditary optic neuropathy, LHON). The inheritance pattern of mitochondrial DNA is, however,

very different from that of nuclear DNA. Mitochondria are exclusively maternally inherited. Therefore, mitochondrial mutations can only be transmitted through females, although they can affect both sexes equally. Genetic assessment of mitochondrial diseases is complicated by the great variability of these disorders and a pedigree that is seldom conclusive of maternal transmission, as many cases are due to sporadic mitochondrial DNA mutations or are determined by nuclear genes.

In Leber hereditary optic neuropathy, the pattern of maternal inheritance is well documented. The commonest mitochondrial DNA mutation is a point mutation in base pair 1178 of the ND4 gene of complex I. Two other common mutations have also been described (G3460A and T14484C), which also involve genes encoding complex I subunits of the respiratory chain. More than 95% of the cases are the result of one of these three mutations. Women with the mutation will transmit it to all offspring, but only around 1 in 2 males and 1 in 10 females with the mutation develop loss of vision. Affected and carrier males do not transmit the mutation to their offspring. An example of a pedigree for a family with Leber's is shown in Figure 8-21.

A single cell contains many copies of the mitochondrial genome, and heteroplasmy for a mitochondrial mutation is usual. Heteroplasmy is the presence in the cell of both the wild-type and mutated copies of the gene. The proportion of mutant mitochondrial DNA in leukocytes is not a reliable indicator of which individuals will develop symptoms. As with other mitochondrial disorders, this presents problems in counseling asymptomatic individuals known to carry the mutation. The recurrence risks for mitochondrial disorders are difficult to determine. Large-scale mitochondrial DNA deletions, as in Kearns–Sayre syndrome, are usually sporadic, while point mutations, as in Leber hereditary optic neuropathy, are more likely to be maternally transmitted.

**FIGURE 8-21** Pedigree showing Leber's Hereditary Neuropathy due to a mitochondrial mutation.

### 8.11.3 Chromosomal Disorders

Factors that indicate the possibility of a familial chromosomal disorder in a pedigree include a family history of infertility, multiple spontaneous abortions, and malformed stillbirths or live-born infants with multiple congenital malformations occurring in a pattern that does not conform to that of Mendelian inheritance. **Figure 8-22** illustrates a kindred in which there is the segregation of a reciprocal translocation in both balanced and unbalanced forms. The possibility of a subtle rearrangement not detected by routine cytogenetic analysis but leading to recurrent chromosome imbalance in offspring should be borne in mind and a number of techniques can be used to identify this situation, such as fluorescence in situ hybridization (FISH), telomere FISH, comparative genomic hybridization, and microarray analysis.

It is difficult to give precise reproductive risks to a person known to carry a balanced reciprocal translocation. The risk of viable chromosome imbalance will depend on the size and origin of the unbalanced segment generated, and there is an association between the mode of ascertainment and the risk of recurrence although this is not absolute. Ascertainment through the live birth of an abnormal baby is associated with a higher risk than ascertainment through miscarriage or infertility. Information from an individual pedigree is seldom sufficient to derive a family-specific risk based on reproductive outcomes in known carriers, and the estimation of risk is mainly based on the likely segregation pattern at meiosis and the chance of an imbalance being viable.

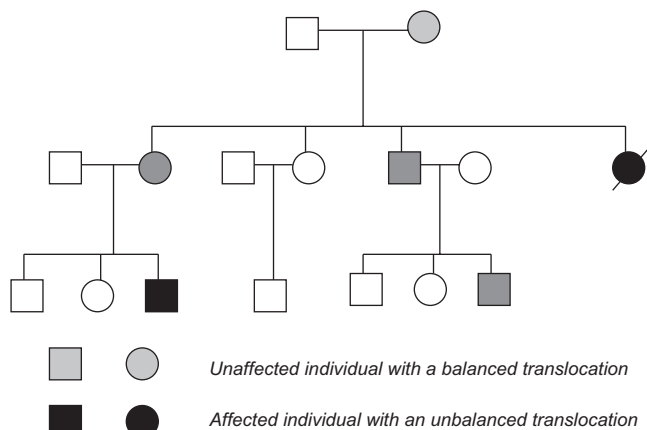

The majority of chromosomal disorders present as sporadic cases. Although very low, the recurrence risk may be increased above the normal age-related risk. After the birth of a child with Down syndrome due to trisomy 21 to a mother under the age of 35 years, the recurrence risk is 0.5% for trisomic Down syndrome and 1% for all chromosomal abnormalities. For mothers over the age of 35 years, the birth of a child with Down syndrome does

not appear to increase recurrence risk significantly compared to the population-related risks. The risk for other family members is not increased.

### 8.11.4 Multifactorial Inheritance

A large group of relatively common disorders have a considerable genetic predisposition, but do not follow clear-cut patterns of inheritance within families. These include many birth defects and chronic diseases of later life. Liability to these disorders appears to be due to the interaction of several genetic and environmental influences. Clusters of cases within a family may simulate a Mendelian pattern of inheritance. It is often difficult to be precise about recurrence risks in multifactorial disorders. The risk is greatest among first-degree relatives, is usually small for second-degree relatives, and often does not exceed the general population risk for third-degree relatives. The risk increases when multiple family members are affected. Risks are also affected by the incidence of the disorder in the general population and the sex of the patient and relatives in disorders that have unequal sex incidence, such as pyloric stenosis and Hirschsprung disease. In these disorders, recurrence is higher in the siblings of the less affected sex probably reflecting a greater genetic load to cause the disease in that sex. The severity of the disorder also influences risk; for example, the recurrence risk is greater for bilateral cleft lip and palate than for unilateral cleft lip alone.

In many disorders, empirical risks have been derived from family studies that provide data on observed recurrences. Risks derived in this way will be less accurate in disorders that are genetically heterogeneous and may not be applicable to populations different from those in which the family studies were performed. Nevertheless, empirical risks provide a useful basis for discussing levels of risk during genetic counseling. Risk tables for some of the common congenital malformations, such as cleft lip, with or without cleft palate, pyloric stenosis, and neural tube defects have been published. Considerable heterogeneity occurs within groups of disorders traditionally considered to be multifactorial or polygenic, such as diabetes, epilepsy, and congenital heart disease, with a proportion of cases attributable to single-gene defects. Identification of a specific genetic etiology, such as the presence of a submicroscopic deletion at chromosome 22q11 in some cases of nonsyndromic congenital heart disease, is important in providing genetic advice appropriate to a particular case. Hirschsprung disease provides a good example of a polygenic disorder in which involvement of several single loci have now been identified in a proportion of families. Data from initial family studies suggested sex-modified polygenic inheritance, and empirical recurrence risks have been produced for genetic counseling based on the sex of the index case and relative

**FIGURE 8-22** Pedigree illustrating the segregation of a balanced and unbalanced reciprocal chromosome translocation.

and the length of the aganglionic segment involved. A mode of inheritance compatible with an incompletely penetrant autosomal-dominant gene was suggested in some families. Linkage to a gene on chromosome 10 was subsequently demonstrated and mutations in the RET oncogene demonstrated. Mutations in other genes, notably the endothelin receptor type B gene, have also been implicated. Thus in a subset of families with Hirschsprung disease, there is a major unifactorial predisposition, a situation likely to be reflected in other multifactorial disorders.

### 8.11.5 Isolated Cases

Many patients presenting to the genetics clinic represent isolated cases within the family, and pedigree information does not contribute to defining the mode of inheritance. Genetic advice in such cases depends on reaching a diagnosis in the affected individual and identifying the underlying etiology. Any of the following situations may apply:

1. The disorder may be due to an autosomal-dominant gene defect, arising by new mutation, transmitted through a nonpenetrant or very mildly affected parent, or by a clinically unaffected parent who carries a mosaic germ line mutation. The situation may also represent nonpaternity. Risk to siblings varies between 0% and 50%, depending on the origin of the mutation, while risk to the offspring of the affected individual would be 50%.
2. The disorder may be caused by an autosomal recessive gene defect with a 25% recurrence risk for siblings unless due to UPD or new mutation. If the carrier state can be confirmed by molecular or biochemical analysis, cascade screening of other family members may be appropriate when the population carrier frequency is high or consanguineous marriages are planned.
3. The disorder may be due to an X-linked gene, usually presenting in a hemizygous male but affecting females if the X-inactivation pattern is skewed or the gene acts dominantly. Isolated cases may represent new mutations, which are frequent in lethal X-linked recessive disorders, or may be transmitted by asymptomatic mothers who are carriers or who have germ line mutations.
4. The disorder may be due to a mitochondrial DNA mutation representing a sporadic case or maternal transmission.
5. The disorder may be due to a chromosomal abnormality. Many of these, including the common trisomies due to nondisjunction, have a low risk of recurrence, but unbalanced karyotypes due to familial chromosomal rearrangements may carry high risks of recurrence, and investigation of the relatives is required.
6. The disorder may be polygenic and recurrence risks depend on the disorder. These are based on empirical data derived from family studies.
7. The disorder may have a nongenetic etiology with no increase in the risk of recurrence, unless due to a teratogenic agent that further pregnancies will also be exposed to.

## Analysis of Genetic Linkage

*Rita M Cantor*

Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

### 9.1 INTRODUCTION TO LINKAGE ANALYSIS

Linkage analysis is a well-established genetic method used to map the genes for heritable traits to their chromosome locations. It is part of a larger process that has been referred to as “reverse genetics,” because the approach works in the reverse order from our model of how genes operate, biologically. That is, while genes act in a forward fashion to produce a trait, reverse genetics starts with the trait and uses linkage analysis along with other analytic methods to identify the predisposing genes. Reverse genetics became feasible in the 1990s, when a very extensive panel of multi-allelic markers that spanned the human genome was established. During the last 10 years, the genome-wide markers in use have evolved from multi-allelic to bi-allelic single nucleotide polymorphisms (SNPs) where their spacing is much denser. The whole genome is analyzed and the approach is referred to as a full genome linkage scan.

The genome-wide markers are genotyped and tested in a study sample of pedigrees and those showing the strongest statistical evidence of linkage exceeding a predetermined threshold localize the trait gene to the chromosome segment where the markers reside. The resolution at the locus is usually quite poor, as many genes will reside within a linked region. Nevertheless, a statistically significant linkage result limits the search for the predisposing gene to those in the linked region, thus reducing cost and follow-up time. Once a trait gene is mapped by linkage, other strategies such as fine mapping, linkage analysis with additional markers and targeted association analysis can be used to further refine the linked region and identify the gene of interest. These methods include linkage analysis with additional markers, targeted association with SNPs, and genetic sequencing. Using the advances made by the Human Genome Project, reverse genetics has been very effective in identifying genes causing rare Mendelian disorders that result from a single gene.

Linkage analysis has two requirements. These are families with individuals who exhibit a heritable trait

of interest and members of the families that have been genotyped for markers. Thus, the first critical step is to establish that the trait of interest is heritable and to assess its mode of inheritance. The hallmark of a heritable trait is that it is shared to a greater degree by genetically close relatives as compared to distant relatives. Comparison of trait concordance rates in monozygotic and dizygotic twin pairs is the classic approach to assess heritability, but other designs have also been used.

In a linkage analysis, the families can vary in size from nuclear families or sibships with at least two genotyped children measured for the trait to large pedigrees with complicated structures in which a substantial percentage of the members are genotyped and measured for the trait. The trait can be binary, having only two values, such as the absence or presence of a disease, or quantitative, continuous, and possibly normally distributed, such as height. Statistical algorithms are applied to the family structure, marker, and trait data to test if a trait value co-segregates with a particular marker allele within each family more often than one would expect by chance alone. The segregating marker allele may differ among families and the results are combined over all of the families. Chromosome regions where statistically greater than expected marker/trait co-segregation occurs are considered to be linked to the trait. The analytic linkage algorithms can be simple or complex and easy or difficult to apply and interpret. The design of a good linkage study involves the consideration and coordination of all of these factors.

For Mendelian traits that follow a pattern of inheritance consistent with a single gene that is X-linked, autosomal recessive, or autosomal dominant, linkage between the trait and the genetic markers is tested using a parametric linkage analysis that models the mode of inheritance of the trait in the analysis. Application of appropriate computer software results in an estimate of a recombination fraction between the trait gene and a chromosome locus. The linked region is usually relatively large, and a statistically successful linkage result is usually followed by fine mapping of additional markers

in the same pedigrees within the linked region. These marker genotypes are analyzed by additional linkage or association tests to better localize the gene. For genetically complex traits, which are discussed in the section addressing model-free linkage analysis, the initial approach is similar to the one used for Mendelian traits, but the mode of inheritance is not known and thus, not specified.

It should be noted, however, that currently many gene identification studies are bypassing linkage analysis. Pedigrees have been reduced to single individuals, genotyping is done with very dense SNP marker panels, and trait genes are identified by testing individual SNPs using the statistical method of association analysis. Rather than testing co-segregation of marker alleles and trait values of individuals within pedigrees, the current studies capitalize on linkage disequilibrium, which is a reflection of the co-segregation of base-pair alleles over many generations due to their very close proximity.

The important underlying biological concepts and statistical methods for conducting and interpreting a linkage analysis are presented in this chapter. A very detailed discussion of the additional aspects and refinements of linkage analysis is provided in the book *Analysis of Human Genetic Linkage* by Jurg Ott listed in the further reading section.

## 9.2 LINKAGE ANALYSIS: BASIC CONCEPTS

Linkage analysis is a statistical procedure to combine data on family structures, trait values, and genetic markers. Its biological basis is the detection of recombination between markers and traits, and a reduced amount of recombination compared to what is expected is the hallmark of linkage. Interpreting this statistically requires an understanding of likelihood functions, maximum likelihood estimation, and odds ratios. These basic concepts and their integration to produce parametric linkage analysis are discussed below.

### 9.2.1 Recombination: Biological Basis of Linkage Analysis

Linkage analysis is based on the biological phenomenon of genetic recombination, which occurs in the parental gametes during the process of meiosis before the eggs and sperm are produced. In a parental gamete, when a pair of chromosomes, one from each grandparent, aligns in the first metaphase, an exchange of chromosome material often occurs via a crossover event, with the crossover location thought to be determined by chance. This recombination of genetic material results in chromosomes different from those that would be inherited from either parent alone. Thus, each child inherits a unique set of chromosomes that are recombinants of the grandparents'. Linkage analysis is based on identifying

recombination events between genetic markers and trait loci and inferring whether a trait and marker alleles are traveling in close proximity on the same chromosome or are further away or on different chromosomes. The fundamental principle of linkage analysis is that for any two loci on the same chromosome, the closer they are to each other, the less likely it is that they will undergo recombination. Linked genes are those located close enough to each other on a chromosome so that an expected crossover rate within the genetic material separating them at meiosis is less than 50%. Although recombination rates are not uniform across the genome, this principle has provided an effective biological model for linkage analysis.

### 9.2.2 Linkage Analysis Simplified: Inbred Mouse Strains

Families segregating a trait of interest are essential for linkage analysis. The patterns of allele frequencies in human genes and their co-segregation derive from millennia of nonexperimental mating, resulting in our current human population. Thus, unlike experiments with inbred mouse strains, all genetic studies in humans can only be observational. However, to illustrate some basic concepts used in linkage analysis, we first discuss the approach in inbred strains where the ideas are very straightforward. How these principles are applied to analyze linkage in human pedigrees is discussed in greater detail later in the chapter.

In experimental species, controlled crosses can be optimally designed to investigate recombination between loci. For two biallelic markers  $A,a$  and  $B,b$ , homozygous parental inbred strains can be crossed, where a phase known genotype of  $AB/AB$  is crossed with a phase known genotype of  $ab/ab$ , yielding a first generation (F1) with phase known  $AB/ab$  individuals where the alleles inherited from each parent are located on distinct chromosomes divided by the line "/" in our notation here. F1 individuals can be crossed back to either parental line, say,  $AB/ab \times AB/AB$  (backcross), or they can be crossed among themselves,  $AB/ab \times AB/ab$  (intercross). Because the chromosomal origin of each allele is unambiguous, recombination events can be directly identified in each offspring by genotyping markers. Consequently, estimation of the recombination fraction,  $r$ , the observed number of crossovers between the two loci divided by the possible number of crossovers in that interval, is very simple to estimate by counting. If the estimate of  $r$  is close to zero, we can infer that the two markers are very close together; while if it is 50%, we can infer that the two markers are very far apart on the same chromosome or they are on different chromosomes. This is because the expected crossover on the same chromosome or reshuffling of chromosomes during meiosis results in a 50% chance of seeing the parental genotype combination in the child. Linkage is inferred when  $r$  is significantly less than 50%.

The option of counting recombinants is usually not possible in humans. A situation analogous to a murine backcross consists of a nuclear family where the observed parental genotypes for markers at two loci are  $AaBb \times aabb$ . Note, however, that the phase of these genotypes is not known for the double heterozygote: that parent may be either  $AB/ab$  or  $Ab/aB$ . This precludes simple counting as a method for estimating  $r$ . Historically, these two possible phases have been called *coupling*  $AB/ab$  and *repulsion*  $Ab/aB$ . The possibilities of coupling and repulsion are modeled by the statistical methods of parametric linkage analysis. Since there is a 50% chance that the gametes are in coupling and a 50% chance they are in repulsion, the evidence for linkage is examined under both assumptions and the evidence is then combined.

### 9.2.3 Parametric Linkage Analysis: Statistical Concepts

The parametric method to sequentially test for linkage in pedigrees was adapted and applied by Newton Morton in his 1955 paper, listed in further reading section. It is a procedure where  $r$  is the parameter of interest, and each pedigree is analyzed separately, using the same analytic algorithm separately at fixed values of  $r$ . The results are combined sequentially over the families that are tested until a decision regarding linkage is reached. Using Morton's sequential linkage approach, linkage is inferred if the evidence from the tested families results in an LOD score, the test statistic, exceeding 3.0 and is ruled out if the LOD score falls below  $-2.0$ . These values are equivalent to the odds of 1000:1 for linkage or 100:1 against linkage, respectively. They are derived from the prior probability of linkage to a region and the multiple tests that are being conducted. Although many new approaches, algorithms, and extensions to the algorithm have been developed since that time, the method remains in use. Since many of the important concepts and approaches to linkage analysis were developed in relation to this algorithm, those concepts are presented in the context of the algorithm to detect parametric linkage.

**9.2.3.1 Likelihoods, Maximum Likelihood Estimation and Statistical Significance.** We begin by defining the concept of likelihood in the context of linkage analysis. In general, if  $H$  is a hypothesis (e.g. two loci are linked with a recombination fraction of  $r$ ) and  $D$  is the data collected to test the hypothesis (marker and trait information in families), statistical theory tells us that the likelihood of this hypothesis,  $L(H)$ , is proportional to the probability of the data when we assume that hypothesis is true,  $p(D|H)$ . Constructing a likelihood  $L(D|H)$  requires representing in symbols a model of how the data (trait phenotypes and marker genotypes generated in the pedigrees) are expected to co-segregate in the families. The principle of maximum likelihood states that the hypothesis or model with greatest value for the likelihood is that for which the probability of

the data that is observed is maximized. For linkage, we assess the value of  $r$  giving the maximum value for the likelihood for the available data. That is, this maximum is obtained by finding that value of  $r$  which makes the probability of the experimental data in the model containing  $r$ ,  $p(D|r)$ , the largest. Originally the likelihoods were calculated for specific values of  $r$  that are 0.01, 0.05, 0.10, 0.20, 0.30, and 0.40. With the advent of efficient computer programs, the maximum likelihood estimate of  $r$  is obtained currently using a numerical approach, where an algorithm or procedure is used to climb the surface of the likelihood until a maximum is reached. Thus  $r$  may not be estimated at any of the fixed values listed above.

As with all estimates derived from a limited sample of experimental data, a significant sampling error is associated with  $r$ , and linkage cannot be inferred from this value alone, even if it is less than 0.5. Rather, a statistical test that contrasts the likelihoods of linkage and independent segregation is conducted. The likelihood of the latter hypothesis is proportional to the probability of the observations when  $r$  is 0.5, which is the null hypothesis of no linkage. The ratio of the likelihoods is  $p(D|\hat{r})/p(D|0.5)$ , which reflects the odds in favor of linkage at the maximum likelihood estimate of  $r$ . The log of this is referred to as the LOD score, discussed below.

**9.2.3.2 LOD Scores.** The LOD score represents the logarithm in base 10 of the odds of linkage of a trait at a recombination fraction  $r$  with a particular marker locus compared to a recombination fraction of 0.5 between the marker and the trait. The term LOD is derived from the first letters in the log of the odds and the method it represents provides a different way of assessing the significance of the linkage signal, other than a  $p$ -value. The LOD score approach was applied by Newton Morton to the linkage problem in his paper presenting the methods in 1955, and is from the field of sequential methods in statistics, where all the evidence is not assessed in one large analysis, but data are collected and used sequentially to reach a decision. This reflects an efficient and economical method for studying families—once a decision is reached it is not necessary to study additional families. In symbols, the LOD score for linkage takes the form  $\log p(D|\hat{r})/p(D|0.5)$ , where  $D$  is the marker and trait data in the families and  $r$  is the recombination fraction. We infer that there is linkage when the LOD score exceeds 3.0, a value that was calculated by Morton by taking into account the fact that any two loci in the whole genome have a certain prior probability of being on the same chromosome. Other criteria have been proposed for more densely spaced markers, and Nyholt has addressed the issue of significance levels for different statistical methods of linkage analyses more fully. Together with the maximum likelihood estimate of the recombination frequency and its associated LOD score, it remains customary to report a LOD score table, where the LOD

score is computed for a set of predetermined recombination fractions of 0.001, 0.01, 0.05, 0.10, 0.20, 0.30, and 0.40. Through this convention, results from independent studies can be combined at these particular recombination fractions without reanalysis of the combined set of families. Once the LOD score exceeds 3.0 at one of the recombination fractions, linkage is declared, and the distance between the trait gene and the marker is inferred to be that recombination fraction among the ones listed above exhibiting the largest LOD score. If  $r$  is 0.05 at the highest LOD score, it means that the trait and the marker are 5 centiMorgans (cM) apart. A Morgan is defined as the distance along a chromosome where exactly one recombination is expected. A cM is 0.01 of a Morgan. A rough rule is that the map distance of a cM is equivalent to one million base pairs in physical distance. Thus, the recombination fraction of 5 represents a distance of 5 million base pairs. There are likely to be many genes in a region of this size, and follow-up work is required to identify the specific gene involved.

**9.2.3.3 Modeling Traits with Penetrance Functions.** Computer software for parametric linkage analyses requires that the mode of inheritance of the trait of interest be specified in terms of the penetrances of the genotypes at the causal gene. To do this, it is usually assumed that the trait gene is biallelic. Penetrance is the probability that the trait genotype will lead to the phenotype of interest, and the penetrance values vary between 0.0 and 1.0. If we assume that the two alleles are  $d$  and  $D$ , the inheritance pattern is modeled by setting the values of the penetrances of the three possible genotypes,  $DD$ ,  $Dd$ , and  $dd$ . In a simple model of a dominant binary trait, the penetrances of  $DD$  and  $Dd$  are each 1.0 in those with the trait. That is, if one or two copies of the disease allele,  $D$ , is present, it will surely lead to disease. Since the  $dd$  genotype will never lead to disease, its penetrance is 0.0. The penetrance values for those without the disease are 0.0, 0.0, and 1.0 for  $DD$ ,  $Dd$ , and  $dd$  respectively. That is, only those with the  $dd$  genotype will develop the disease. For a recessive disorder, where  $D$  is again the disease allele, the penetrances for  $DD$ ,  $Dd$ , and  $dd$  in those with the disease are 1.0, 0.0, and 0.0 respectively

and in those without it are 0.0, 1.0, and 1.0 respectively. These very simple models ignore the possibility of alternative disease predisposing genes, phenocopies that do not have a genetic basis for the phenotype but exhibit it anyway, and reduced penetrance where the predisposing genotypes result in the disease only some of the time.

**9.2.3.4 Designing and Conducting Parametric Linkage Analyses.** The purpose of linkage analysis is to accrue statistical evidence regarding the co-segregation of a trait and marker alleles within families. It should be noted that the trait can co-segregate with a different marker allele in each family and linkage would be established. Thus, to begin selecting families, each would be chosen because some members have the trait of interest. Mendelian traits that have a known mode of inheritance and are relatively rare are investigated in extended families. This is particularly true if they are recessive conditions in population isolates with few founders or dominant fully penetrant traits where trait and marker inheritances can be followed along extended lineages within the families. In addition, for a rare condition, ascertainment of large pedigrees is usually the only way a substantial number of affected individuals can be obtained for linkage analysis. Linkage analysis of large pedigrees is usually performed with the assistance of computer programs such as LINKAGE and SAGE/LODPAL. Tables 9-1 and 9-2 give some of the most commonly used computer programs that are used to test for parametric linkage. Here, the LINKAGE software is appropriate for the analysis of binary traits in large pedigrees. Other programs, such as Option 2 of Mendel will conduct the same analysis, although the format of the input files and output reports of the programs may differ.

Regarding the selection of families for a study sample, knowledge about the mode of inheritance should have the greatest influence. Families that include individuals who are inbred recessive homozygotes for traits of interest provide a powerful study design when they can be ascertained. It is also important to recognize that informative families are those that are segregating the trait in all branches so that the ability to detect the trait in each branch of the family is an important first step before collecting and

**TABLE 9-1 Linkage Analysis Software for Binary Traits in Large Pedigrees and Nuclear Families Indicating Whether the Analysis Is Parametric and Model Based or Model Free**

Linkage of Binary Traits in	Program Name	Model	Extra Features
Large pedigrees	LINKAGE	Based	HOMOG: locus homogeneity testing

genotyping DNA. It is also important to recognize that a single individual in a sibship where phase is not known will not provide information regarding linkage.

### 9.3 EXTENDING PARAMETRIC LINKAGE ANALYSIS

Since it was developed, methods and computer programs have been included to make linkage analyses more precise and powerful. Their applications are discussed here. First, the methods used to test linkage for a Mendelian binary trait have been extended to model the inheritance of traits that result from a single gene, but the trait genotypes have penetrance values that are neither 0 nor 1. This occurs when the risk genotypes do not always lead to the development of the trait (reduced penetrance) or when there are people who exhibit the trait but do not have the trait genotype (phenocopies). Second, the methods have also been extended to reflect genetic heterogeneity, the existence of genes at other loci leading to the development of the same trait. If it is not recognized, genetic heterogeneity can mask a true linkage signal. Third, incorporating the genetic information from several markers simultaneously can improve the linkage signal and better localize the trait gene. Multipoint analyses accomplish this goal. Each of these important factors is discussed below.

#### 9.3.1 Incomplete Penetrance and Phenocopies

Penetrance specifies the probability that an individual with one of the possible trait genotypes will exhibit the trait. Age of onset or gender-specific trait risks can be incorporated with a penetrance model through multiple liability classes with differing penetrance estimates. For example, disease penetrances for DD, Dd, and dd can be 80%, 40%, and 10% in males and 20%, 10%, and 2% in females. For unaffecteds, the DD, Dd, and dd penetrances would be 20%, 60%, and 90% in males and 80%, 90%, and 98% in females, as the two penetrances within a liability class for a given genotype must always sum to 1.0. Phenocopies reflect the occurrence of a trait undistinguishable from the trait of interest, but resulting from other causes. A phenocopy rate can be

incorporated by assuming that affected individuals with a normal genotype have a small probability of expressing the disease, such as 5%. The power of linkage analysis can be affected significantly by phenocopies when they account for more than a small percentage of the cases. If penetrance values are unknown, the careful investigator will take the precaution of verifying that his or her inference of linkage does not critically depend on the assumed penetrances, by testing linkage over a reasonable range of penetrance estimates.

#### 9.3.2 Genetic Heterogeneity

Defining inherited conditions solely on the basis of their clinical manifestations may obscure the fact that the trait under analysis is the result of distinct genetic etiologies that segregate among the families. Unless the trait is the result of different alleles at a single locus, heterogeneity may drastically reduce the power of a linkage analysis when it is not considered. There are several ways to address this. The first is to make a predefined partition of the families using a particular form of the phenotype or a factor such as their ethnicities. One then conducts a linkage analysis in each group separately and reports the results for each group. At a particular locus, one can establish locus heterogeneity by also testing for linkage in the entire sample. Using these three linkage analyses at a single locus, a likelihood ratio test is constructed, contrasting the product of the maximized likelihoods in each subset to the maximum likelihood obtained for the total sample. The test statistic is represented by  $2 \log_e [\Pi_i p(D_i|r_i)/p(D|r)]$ , where  $i$  indexes the two sets of families. That is twice the natural log of the product of the likelihoods of the two data sets with two different recombination fractions compared to the likelihood of all of the data combined with a single recombination fraction. Under the null hypothesis of homogeneity, a single recombination fraction, this statistic follows a  $\chi^2$  distribution with  $n-1$  df (degree of freedom). Here  $n$  is the number of classes into which the data have been partitioned, which is 2 in this case, resulting in 1 df.

A more formal statistical approach to modeling and estimating the degree of heterogeneity among a sample of families is available through the LINKAGE software referred to as HOMOG. Here a test of heterogeneity can

be used when the alternative to homogeneity is that the families belong to two etiologic classes, one linked and the other unlinked to the marker locus, although they do not have to be divided a priori as with the test described above. Assuming that a proportion,  $m$ , of the families exhibit linkage while  $1 - m$  are unlinked, the likelihood of the observations can be expressed in terms of two parameters, the recombination fraction  $r$  for the linked form and the admixture proportion,  $m$ . A likelihood ratio test can be formulated by contrasting the likelihood obtained when both parameters are estimated to that obtained under the hypothesis of homogeneity, where  $m$  is fixed to unity and only the recombination fraction,  $r$ , is estimated. This follows a  $\chi^2$  distribution with 1 df. The two parameters  $m$  and  $r$  can be estimated simultaneously. For tests of locus heterogeneity involving more than two independent sampling units, greater power is expected for the admixture test than for the predivided sample test, because of the smaller number of degrees of freedom allowed in the test.

### 9.3.3 Multipoint Parametric Linkage Analysis: Location Scores

When conducting a linkage analysis, combining the information from several markers from the same chromosome region simultaneously imparts greater statistical power to detect linkage and provides a more precise localization of the trait gene than when the markers are analyzed separately. The distribution of heterozygosity among the markers will add information regarding linkage of the trait under analysis. Information regarding the location and order of markers used in the analyses is provided by a number of online databases such as the one at National Center for Biotechnology Information. Multipoint analyses are based on more complex probability models than single point. The parameters in the likelihood represent all of the between-locus recombination fractions among markers. Maximum likelihood methods, however, still apply and are used to estimate the recombination fractions between the trait locus and the points along the genetic map of markers in the analysis. The resulting calculations are computationally intensive, but can be carried out using software packages such as MENDEL and SAGE/MLOD. As the trait locus is moved across the marker region, the locus with the largest multipoint LOD score or location score localizes the trait gene to a more refined region than conducting several two point analyses can accomplish.

## 9.4 LINKAGE ANALYSIS FOR COMPLEX AND QUANTITATIVE TRAITS

Linkage analysis has also been extended to include traits that are not Mendelian or binary. Following the completion of the Human Genome Project, the remarkable success in identifying genes for Mendelian disorders

resulted in a gradual shift toward analyzing traits with complex inheritance patterns. Since parametric linkage analysis is not well suited for genetically complex traits, model-free linkage analysis, where a model of inheritance is not known and therefore not included in the analysis, has been conducted. Complexity may derive from something as simple as two disease loci, each exhibiting reduced penetrance, to something as complex as each family with the trait having risk alleles in each 10 possible genes, and requiring one of a large number of environmental triggers. The analyses of both traits are conducted using the same model-free analytic methods. In addition, there has been an interest in the genetics of quantitative traits that may be important on their own or correlate with binary traits of interest. Methods and computer programs have been developed to identify the genetics of these traits as well.

### 9.4.1 Model-Free Linkage Analysis

Model-free methods test if the allele sharing patterns in families are consistent with linkage in a very general way. That is, those in the pedigree who have the trait should display evidence of marker allele sharing to a greater degree than one would expect by chance alone in the linked regions. Most model-free tests only include individuals with the trait of interest. However, genotypes of their relatives are important to make more precise estimates of allele sharing. Using a study sample with the trait reduces the risk of including individuals who do not have the trait but share alleles with those who do. Including them in the analysis would mask evidence of linkage. The most common model-free test statistics is based on allele sharing in sibling pairs. Limiting the analysis to sibling pairs has been effective because it is usually difficult to ascertain larger pedigrees with multiple members having the trait if it is complex. In addition, with multiple common risk alleles, members of large families may develop the trait as the result of several genetic etiologies, thus introducing within pedigree heterogeneity, for which we do not have appropriate analytic approaches. Sibling pairs with a trait are usually available for study and are more likely to have the trait due to a shared genetic etiology. Nuclear families contain less information about linkage than a large pedigree, and thus a larger number of them will have to be studied to find linkage.

The sib-pair allele sharing linkage methods are based on a simple expectation. At a marker, the sibling pairs can inherit four possible alleles from their parents. If there is no gene predisposing to the trait in the region of the marker, the sibling pairs should share 0 alleles 25% of the time, 1 allele 50% of the time, and both alleles 25% of the time. The expected proportion of allele sharing is 50%. A significant deviation from these theoretical values at a marker provides evidence of linkage of the trait to that marker. For model-free analyses, the recombination fraction between the marker and the trait gene is

assumed to be zero.  $R$  is not included in the analysis. For several linkage statistics, the degree of allele sharing for each sibling pair is assessed, and the allele sharing estimates are averaged over the pairs. These individual estimates would be 0,  $\frac{1}{2}$ , or 1 for each pair if the genotypes were fully informative and all parents were completely genotyped. When data are missing or the parental genotypes do not allow for an unambiguous assignment of their inheritance, the marker allele frequencies are used in the estimate of allele sharing. The allele sharing estimates will usually be different from 0,  $\frac{1}{2}$ , or 1 to reflect this. In the simplest case, the average allele sharing value is tested against its theoretical value of  $\frac{1}{2}$ . An additional consideration is that if there are greater than two siblings in a sibship, the pairs will not provide statistically independent allele sharing estimates. A weighting scheme to account for this can be employed. For example, three sibs in a sibship contribute information from 3 pairs, and since the information for the third pair can be derived from the first 2 pairs, allele sharing for these 3 pairs can be weighted by a factor of  $\frac{2}{3}$ . A subset of the programs listed in Table 9-1 implement model-free allele sharing linkage methods for binary traits in nuclear families. They are the SIBPAL program of SAGE, the MLS and NPL options of GENEHUNTER, and the MERLIN REGRESS program. These software packages allow for generation of the allele sharing test statistics at evenly spaced intervals along the entire chromosome, given the marker map, and a multipoint analysis is conducted for each chromosome. The packages provide plots of the statistical significance of the tests across the chromosomes so that the loci with significant evidence for linkage can be identified easily.

### 9.4.2 Linkage Analysis of Quantitative Traits

A quantitative trait has can be dichotomized into one that is binary for a parametric linkage analysis. For example, a systolic blood pressure of greater than 140 is used to classify an individual as hypertensive and hypertension has often been the trait tested for linkage. In fact, the quantitative trait itself may be better suited for linkage analysis than the dichotomized trait, as the extent of variation can be assessed in all family members, thus making it likely to provide increased statistical power to detect genes. In addition, the etiology heterogeneity of genetically complex traits may be reduced by the analysis of a correlated quantitative trait that reflects only one feature of the complex disorder. For example, cardiovascular disease may be better addressed by studying a particular lipid trait, such as cholesterol, rather than the binary trait of a myocardial infarction, which is very likely to have a much broader etiology. Programs to analyze quantitative traits in large pedigrees usually require the assumption of trait normality while those for smaller pedigrees do not require

the rigorous adherence to these assumptions. Programs and their features are given in Table 9-2.

Variation in a quantitative trait usually results from the contributions of multiple genes with small effects modified by environmental influences. If none of the genes contributes a substantial amount to this quantitative variation, loci can be difficult to detect using linkage analysis. However, a gene contributing to a relatively large proportion of the variance of the trait, a major gene, is a good candidate for localization by quantitative trait linkage analysis. When conducting a quantitative trait linkage analysis, it is important to select families for which the trait exhibits marked variation within the pedigree. Those families having multiple members with extreme values of the trait are most likely to provide support for a major gene. Regions that are identified by the linkage analysis of a quantitative trait are usually referred to as quantitative trait loci or QTL.

A list of computer software commonly used for the linkage analysis of quantitative traits is given in Table 9-2. A variance component analysis of a quantitative trait, such as that conducted by the SOLAR software, identifies linked chromosome regions by decomposing the variance of the trait into the components that contribute to it. The log of the ratio of the likelihood of the data with a major gene is compared to the likelihood of the data when there is no major gene modeled at that location. Normality of the trait distribution is an important assumption and if the trait is not normally distributed, transformation to normality is critical to a successful analysis. For non-normal traits in smaller pedigrees, GENEHUNTER/MAPMAKERS-IBS, MERLIN/REGRESS, and SAGE/SIBPAL provide good alternatives. GENEHUNTER/NPL, which uses a nonparametric method that ranks the trait values, is robust against non-normality. The ordered subset analysis approach implemented in OSA can be used to identify QTL for quantitative traits that are correlated with binary traits. The families in the analysis are ordered according to their scores on a quantitative correlated value and the evidence for linkage is assessed as the ordered families are sequentially included in the analysis.

## 9.5 LINKAGE ANALYSIS: FUTURE DIRECTIONS

Linkage analysis has been used to identify chromosome locations of human trait genes for more than 50 years. Its well-developed tools include families, markers, and statistical methods of analysis. The genes for many Mendelian disorders have been identified with these tools. However, as the number of genetic markers increased from 30 to 2.4 million, our ability and enthusiasm to localize and identify genes for traits of increasing genetic complexity has grown proportionally. Such marker

density allows us to capitalize on linkage disequilibrium to identify trait genes, and consequently, during the past 10 years, there have been few modifications to the well-established linkage methods. The primary approach to gene identification has quickly transitioned to genome-wide association studies (GWAS), which capitalizes on the linkage disequilibrium among closely spaced markers in populations. In some sense, analyzing linkage disequilibrium in populations is similar to analyzing linkage in families. To clarify, in the current generation, within a population, SNP alleles are in linkage disequilibrium because they are too close to each other on the chromosomes to have undergone significant recombination over the generations. Thus, one can view GWAS as linkage analyses of a large pedigree that is the current population under analysis. All mapping information is in the current generation, and we test for association of specific marker alleles and the trait of interest.

GWAS are based on association tests of common SNP variants whose frequencies are larger than 5%. The genotyped SNPs have been selected to tag trait variants that may not be tested directly. Although consistent gene associations have been identified for a substantial number of complex traits, their effects have been surprisingly small. Successful GWAS have required very large samples, and the detected effect sizes indicate that the risk is only raised by about 10–20% compared to that of the background genotype. Consequently, the genetics literature has expressed concern that GWAS have not revealed the etiologies of traits with significant heritabilities.

Recently, concern about the small effect sizes of common variants, as well as the dramatic reduction in the cost of whole exome sequencing with “next generation” methods has refocused the interest of many of those studying complex disorders toward the detection of rare genetic variants via sequencing. These variants are expected to have a frequency less than 1%, and may even consist of private mutations. They are also expected to exhibit greater penetrance values and effect sizes than the common variants. To sort through the many variants likely to be uncovered, there has been a renewed interest in the study of large pedigrees. If they exist for a complex trait, analyses will be focused on identifying those pedigrees that segregate the trait where it is acting in a quasi-Mendelian fashion. As with Mendelian disorders, model-based linkage analysis that allows for reduced penetrance and phenocopies may reveal important loci.

Targeted sequencing in linked regions could reveal the genes with the segregating rare variants. With this approach, parametric linkage analysis is likely to again become a natural first step in gene finding efforts over the next few years.

### Biography

**Dr Rita Cantor** is a statistical geneticist and a professor of Human Genetics and Psychiatry in the David Geffen School of Medicine at UCLA. With a background in mathematics, statistics, and genetics, her research efforts have been devoted to developing and applying statistical methods in order to reveal the etiologies of genetic disorders. In 1980, she began this work as a postdoctoral fellow in Human Genetics at the Medical College of Virginia by analyzing data from twin studies. At that time, genetic marker data were rare. As the field of genetic epidemiology evolved, she moved to Cedars-Sinai Medical Center and then joined the new Department of Human Genetics at UCLA. During that time she conducted and participated in genome-wide linkage and association studies for both Mendelian and genetically complex disorders. Her current focus is on the genetically complex traits defined by autism spectrum and other psychiatric disorders, coronary artery disease, and systemic lupus erythematosus. The massive amount of data generated by sequencing to identify rare variants will help define her future analytic approaches.

# CHAPTER 10

## Chromosomal Basis of Inheritance

*Fady M Mikhail*

Cytogenetics Laboratory; Department of Genetics, University of Alabama at Birmingham, Birmingham, AL, USA

This article is a revision of the previous edition article by Julie R Korenberg, T K Mohandas, volume 1, pp 167–190, © 2007, Elsevier Ltd.

### 10.1 INTRODUCTION

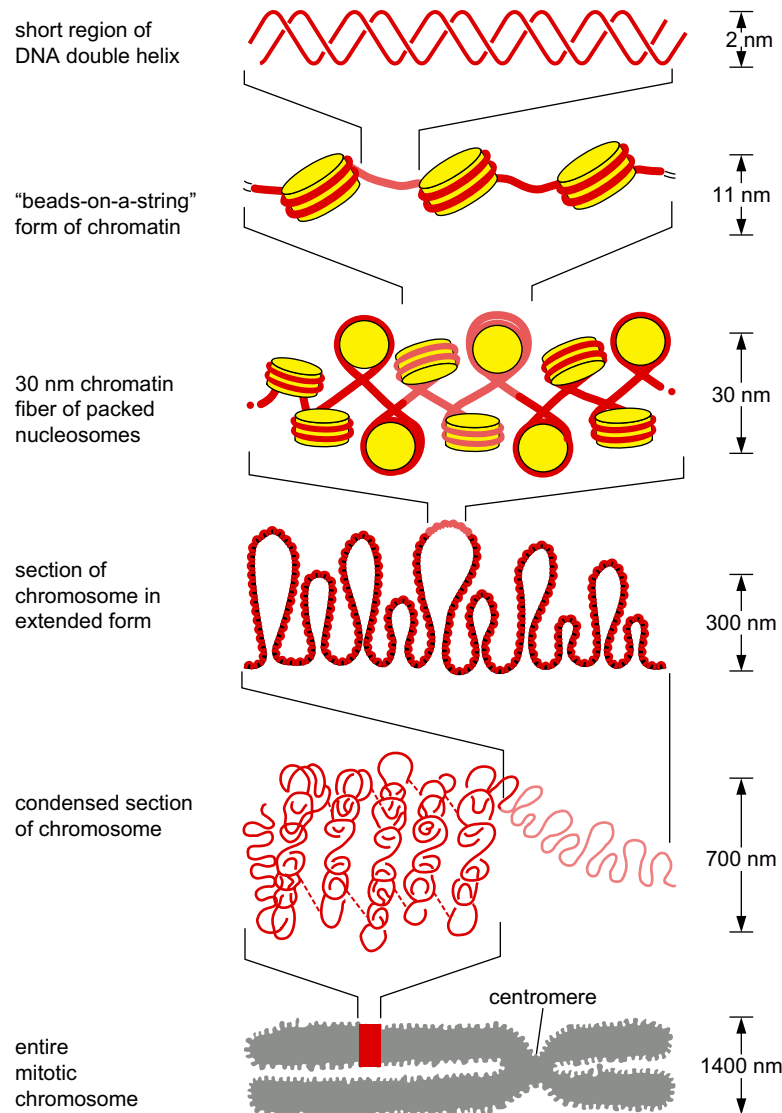

The human genome is packaged into a set of chromosomes as in other eukaryotes. Chromosomes are thus the vehicles of inheritance as they contain virtually the entire cellular DNA with the exception of the small fraction present in the mitochondria. The structure, function, and behavior of chromosomes are therefore of much interest and importance. Chromosomes are derived in equal numbers from the mother and father. Each ovum and sperm contains a set of 23 different chromosomes, which is the haploid number ( $n$ ) of chromosomes in humans. The diploid fertilized egg and virtually every cell of the body arising from it has two haploid sets of chromosomes, resulting in the diploid human chromosome number ( $2n$ ) of 46. The human karyotype consists of 22 pairs of autosomes and a pair of sex chromosomes. The correct chromosome number in humans was determined and confirmed in 1956 (1,2).

The behavior of chromosomes in meiotic cell divisions provides the basis for the Mendelian laws of inheritance, whereas their abnormal behavior in cell division leads to abnormalities of chromosome number. In this chapter, we examine the current understanding of the structure, molecular organization, and behavior of human chromosomes and explore how these features contribute to chromosomal diseases.

### 10.2 CHROMOSOME STRUCTURE

Although the structure of human and other eukaryotic chromosomes is not understood in full detail, recent investigations have provided insights into several aspects of chromosome structure at the molecular level. The haploid human genome consists of about  $3 \times 10^9$  base pairs (bp) of DNA. Since 3000 bp of naked DNA are  $\sim 1 \mu\text{m}$  long, the total length of the diploid human genome is

about 2 m. As the cell nucleus is no more than  $10 \mu\text{m}$  in diameter, it is necessary to fold and compact this DNA, which is accomplished by packaging it in a hierarchy of levels into chromosomes of manageable size (Figure 10-1). Organization of the DNA into chromosomes also maintains the linear order of genes and facilitates faithful replication and segregation of genetic material during cell division. The first level of this packaging, and thus the fundamental unit of chromosome organization, is a regularly repeating protein-DNA complex called the nucleosome. The basic structural features of the nucleosome were established in the early 1970s and have been further confirmed by high-resolution analysis of its crystal structure (3). The nucleosome has the same design in all eukaryotes and consists of a cylindrical core of about 11 nm in diameter and 6 nm in height made up of two molecules each of the four core histones (H2A, H2B, H3, and H4) with 147 bp of DNA wrapped around it. A “linker” DNA connects adjacent nucleosomes. Each nucleosome is also associated with a molecule of histone H1, which changes the path of the DNA as it exits from the nucleosome, and plays a role in further condensation of chromosomal DNA. Formation of the nucleosomes achieves a sevenfold compaction of the DNA double-helix. The next higher level of packaging is the chromatin fiber, visible by standard electron microscopy. This is a superhelix, 30 nm in diameter, composed of nucleosomes and histone H1. The 30 nm fiber is the basic component of interphase chromatin and metaphase chromosomes. Two models have been proposed for the formation of the 30 nm chromatin fiber. In the first model, called the “solenoid,” consecutive nucleosomes are located next to each other in the fiber, folding into a simple one-start helix (4). Subsequently, a second model of the “two-start helix” was proposed on the basis of microscopic observations of isolated nucleosomes (5). Although some variations exist in this model, essentially nucleosomes

**FIGURE 10-1** Various levels of DNA packaging in the cell. (Alberts, B., Johnson, A., Lewis, J., et al. *Part II: Basic Genetic Mechanisms, Chapter 4: DNA and Chromosomes, The Global Structure of Chromosomes, Figure 4-55: Chromatin Packing. In Molecular Biology of the Cell, 4th ed.; Garland Science: New York, 2002.*)

are arranged in a “zigzag” manner, such that a nucleosome in the fiber is bound to the second neighbor, but not the first (6–8). Very recently, it was shown that the two-start zigzag and one-start solenoid models may be present simultaneously in a 30 nm chromatin fiber under certain conditions (9). The structural details of the 30 nm chromatin fiber remain controversial. Formation of the 30 nm chromatin fiber achieves a nearly 50-fold compaction of the DNA double-helix. Short AT-rich regions referred to as matrix attachment regions (MARs) that occur at about every 30–150 kb of DNA anchor the chromatin fiber to the proteins of the nuclear matrix of the interphase nucleus. Topoisomerase II, an enzyme that induces transient double-strand breaks in DNA and permits uncoiling of the two strands of the DNA duplex, is a major matrix protein. At the next level of packaging, the 30 nm chromatin fiber is arranged into loops that radiate from a core or scaffold of the metaphase chromosome. The MARs are also the site for attachment of

the chromatin fiber to the nonhistone protein scaffold of the metaphase chromosome (hence also called scaffold attachment regions) (10). Topoisomerase II is a component of the chromosome scaffold and has been shown to play a role in chromosome condensation. The other major component of the metaphase chromosome scaffold that also plays a key role in chromosome condensation is the condensin complex, a member of the SMC (structural maintenance of chromosomes) family of proteins (11). Other members of the SMC family of proteins mediate chromosomal functions such as sister chromatid cohesion (cohesin complex) and DNA-repair (11). Besides topoisomerase II and condensins, cations are also believed to be essential participants in chromosome condensation (12,13). The details of the higher order structure of chromosomes are not well understood at the molecular level. However, it is clear that each chromosome contains only a single very long duplex of DNA with an estimated packaging ratio of about 1:10,000. At

the highest level of compaction, the metaphase–anaphase chromosomes are most easily movable by the spindle apparatus during cell division.

### 10.3 CHROMOSOMES IN CELL DIVISION

Cell division and proliferation are central to growth and development of multicellular organisms. The major events in the cell cycle are replication and segregation of chromosomes. Cell division also ensures proper segregation and partitioning of the genetic material into daughter cells, thus providing the basis for Mendelian laws of inheritance. The cytologic aspects of mitosis and meiosis, the two forms of cell division in eukaryotes, have been described in great detail in numerous studies in the past. However, the explosive growth of molecular biology in the last 20 years has brought the study of mitosis and meiosis to the forefront again. These investigations have elucidated biochemical aspects of cell cycle biology and chromosome mechanics (14,15). This section describes the essential features of mitosis and meiosis relevant to inheritance. Knowledge of these features is crucial for understanding the Mendelian laws of inheritance, construction of genetic maps, and the origin of chromosome aberrations.

#### 10.3.1 Mitosis

In somatic cells, and in cells of the germline prior to the time they undergo their first specialized meiotic divisions, nuclear division takes place by a process called mitosis. During mitosis, each chromosome divides into two daughter chromosomes (sister chromatids), one of which segregates into each daughter cell. Therefore, the number of chromosomes per nucleus remains unchanged producing daughter cells with identical chromosome constitutions. In cells with a generation time of 18–24 h, mitosis takes about 1–2 h and is divided into five major stages: prophase, prometaphase, metaphase, anaphase, and telophase (Figure 10-2).

In the initial phase of mitosis, prophase, the chromosomes become visible as a result of condensation that continues throughout this phase. Each chromosome has already undergone replication during the preceding interphase, generating two sister chromatids that will become daughter chromosomes. The sister chromatids are closely held together along their length by cohesins until anaphase. The centrioles duplicate during the S phase and move apart to occupy positions at opposite ends of the cell, defining the poles of the mitotic spindle.

During prometaphase, the nuclear membrane begins to disintegrate, allowing the chromosomes to spread around the cell. In metaphase, the chromosomes become attached to microtubules of the mitotic spindle at their centromeres and undergo movements that lead to their alignment in the equatorial plane of the spindle. At this stage, the chromosomes have reached their maximum state of condensation.

Anaphase begins after the chromosomes are fully aligned on the metaphase plate. Each pair of sister

chromatids separates as cohesion is lost, first along the arms and finally at the centromere of each chromosome. The resultant daughter chromosomes move toward opposite poles of the spindle as a result of microtubule dynamics and the action of motor proteins. Recent research has provided insights into the molecular biology of chromosome separation. The two sister chromatids of a chromosome are held together following chromosome replication by cohesins. This is a multi-subunit protein complex that ensures correct segregation of daughter chromosomes at anaphase. At the beginning of anaphase, the cohesin complex is cleaved by a protease called separase, allowing separation of the sister chromatids (16).

At telophase, each set of daughter chromosomes arrives at the centriole at the ends of the mitotic spindle, and reconstitution of the nuclear membrane begins. Cytokinesis, the division of the cytoplasm, follows telophase and leads to the formation of two genetically identical daughter cells.

#### 10.3.2 Meiosis

Meiosis is a specialized cell division in germ cells that generates gametes with the haploid set of 23 chromosomes. The final gametic set includes single representatives of each of the 23 chromosome pairs selected at random. The details of meiosis and gamete formation are somewhat different in males and females, but the basic features are the same in both and are of fundamental importance. Meiosis accounts for the major principles of Mendelian genetics: segregation, independent assortment, and recombination of linked genes. Recombination or crossing over is the exchange of genetic material between homologous non-sister chromatids, a process that adds to genetic diversity by generating new combinations of genes.

Meiosis consists of two cell divisions (meiosis I and II) and is distinguished from mitosis by the following:

1. Homologous pairing: Maternal and paternal homologs of each chromosome are replicated and then undergo exact pairing along their lengths during prophase of meiosis I. Such a paired unit is called a “bivalent” because there are only two centromeres, although it is composed of four chromatids.
2. Recombination (crossing over): Crossing over occurs at the four-strand stage between non-sister chromatids, that is, chromatids from each of the pair of homologous chromosomes. The probability of recombination increases with the physical distance between two chromosomal sites and therefore provides a basis for the genetic map.
3. Segregation of maternal and paternal homologs: Centromeres do not divide at the first meiotic division (meiosis I). Instead, the members of a homologous pair go to opposite poles at anaphase of the first meiotic division. This accounts for Mendel’s first law, the segregation of homologous genetic units.

**FIGURE 10-2** Diagrammatic representation of the stages of mitosis. (Alberts, B., Johnson, A., Lewis, J., et al. Part IV: Internal Organization of the Cell, Chapter 18: The Mechanics of Cell Division, An Overview of M Phase, Panel 18-1: The Principal Stages of M Phase. In Molecular Biology of the Cell, 4th ed.; Garland Science: New York, 2002.)

The segregation of maternal and paternal homologs in each bivalent chromosome pair occurs independently of the segregation in all the other bivalents. That is, the segregation of chromosome 1 homologs is independent of that of chromosome 2 homologs and so on. This accounts for Mendel's second law of independent assortment of genes. Meiosis I also leads to a reduction in the number of chromosomes from the diploid number ( $2n = 46$ ) to the haploid number ( $n = 23$ ) in the gametes.

4. Division of the haploid set with centromere division: The second meiotic division (meiosis II) occurs without a preceding round of DNA synthesis and chromosome duplication. In meiosis II, the two chromatids of a chromosome move to opposite daughter cells.

Meiotic prophase I is rather prolonged and can be subdivided into five stages on the basis of condensation of chromosomes and the extent of homologous pairing: leptotene, zygotene, pachytene, diplotene, and diakinesis. In

leptotene, the chromosomes start to condense and are visible as long threads but the homologs are still not paired. Chromosomal condensation continues and pairing of homologs (synapsis) begins at zygotene and is completed at pachytene, the stage at which recombination occurs (Figure 10-3). By the pachytene stage, synapsis between homologs is completed and crossing over between non-sister chromatids occurs, during which homologous regions of DNA are exchanged. Synapsis is thought to be mediated and stabilized by the formation of the synaptonemal complex (SC) between homologous chromosomes. The SC is a protein-rich ladder-like structure that has a central element flanked by two lateral elements. The lateral elements and the central element are held together by transverse filaments. The lateral elements are formed of the axial elements of sister chromatids of the paired homologs, and the bulk of the chromosomal DNA is found in chromatin loops emanating from the outer sides of the two lateral elements. Initially, the SC was characterized by ultrastructural analysis. More recent studies have identified several protein components of the SC, although the functions of many of these are unknown. A constituent of the lateral elements is cohesin, consistent with the fact that the sister chromatids of each of the homologs are held together at pachytene. Another interesting feature of SC is the presence of recombination nodules along its length. These are thought to be enzyme complexes that mediate genetic recombination via DNA breakage and repair. Chiasmata or cruciform structures become visible at the more condensed diplotene stage as cohesion is lost along the chromosome arms except at each chiasma, the point of recombination between homologous chromosomes.

Chiasmata are still visible at diakinesis, the stage of maximal condensation, and can be used to determine the frequency as well as location of recombination. Chiasmata, like their underlying recombination events, play an important role in the normal segregation (disjunction) of homologs, and each pair of homologs has at least one chiasma per chromosome arm. Moreover, failure of chiasma formation predisposes to nondisjunction of homologs.

During prophase I in males, pairing and crossing over between the X and Y chromosomes is possible because of a small region of homology at the terminal ends of their arms (i.e. pseudoautosomal regions). The two chromosomes pair and cross over in these regions during prophase I.

In meiotic metaphase I, the nuclear membrane disappears and the chromosomes become aligned on the equatorial plane of the cell where they have become attached to the spindle, as in metaphase of mitosis. Then in anaphase I, the chromosomes now separate to opposite poles of the cell as the spindle contracts. In telophase I, each set of haploid chromosomes has now separated completely to opposite ends of the cell, which cleaves into two daughter gametes, so-called secondary spermatocytes or oocytes.

The meiosis II division resembles an ordinary mitotic division, except for the presence of a single set of 23 duplicated chromosomes, each with two chromatids held together at their centromeres. Also, meiosis II is not strictly a genetically equal division as the two chromatids of a chromosome may not be identical as a result of genetic exchange(s) with a non-sister chromatid. At the end of the two meiotic divisions, each primary spermatocyte or oocyte has given rise to four haploid products (see Figure 10-3). Their fate is rather different in males and females, as discussed later.

### 10.3.3 Spermatogenesis and Oogenesis

In the human male, the production of sperms begins at puberty and continues throughout life. Undifferentiated stem cells of the germline, the spermatogonia, are abundant in the seminiferous tubules of the testis and show a high rate of mitotic activity throughout the adult life of a normal male. Of the two types of spermatogonia, only type A can differentiate into primary spermatocytes that enter meiosis, whereas type B are the long-lived progenitors that divide to generate daughter cells of both types A and B. In meiosis, each diploid spermatocyte gives rise to four haploid cells, each of which differentiates into a functional sperm. The entire process, from spermatogonium to sperm, takes about 70 days. The rate of sperm production may be as high as 50–100 million per day over many years, and thus the parental spermatogonia undergo many successive mitoses. It is estimated that the number of mitoses before sperm production in a 20-year-old male is about 200, while in a 45-year-old it is about 800 (17). This provides the opportunity for the occurrence of more adverse genetic change with age in males, which is reflected in an increased mutation rate for certain inherited diseases.

The behavior of germline cells in the female is quite different from that in the male. By about the fourth month of prenatal development, about seven million oogonia have begun to develop into primary oocytes and to enter meiosis. Primary oocytes proceed only as far as prophase of meiosis I by the time of birth, where they remain until ovulation. This suspended stage of prophase occurs after pachytene, is referred to as dictyotene, and lasts from birth until after puberty, when small cohorts of the germ cells progress further into meiosis. The first meiotic division is stimulated by ovulation and is an unequal division in that most of the cytoplasm remains in the ovum and very little is pinched off to enter the first polar body, containing one set of homologs. Sperm penetration of the ovum stimulates the second meiotic division, leading to formation of the second polar body that contains a haploid set of chromosomes. On average, one oocyte per ovarian cycle completes the first meiotic division and proceeds to metaphase of the second meiotic division; if fertilized by a sperm, it completes the second division and embryonic development ensues. Thus, over the approximate 30 year reproductive lifetime of a female,

only a few hundred oocytes complete the first meiotic division and few—if any—complete the second (18).

It is of interest to note that the frequency of point mutations and structural chromosomal changes is in general higher in male gametes and increases with age. This increased mutation rate in males is attributed to the much larger number of cell divisions in the male

germline. In contrast, changes of chromosome number increase with age in female gametes. Errors of disjunction seen with advanced maternal age appear to be related to the 13–50 years the oocytes spend in prophase before chromosome segregation. Genetic mapping studies indicate that the number as well as the positioning of crossover events influence meiotic segregation of

**FIGURE 10-3** Diagrammatic representation of the stages of meiosis. (Turnpenny, P. D., Ellard, S., Chapter 3: Chromosomes and Cell Division, Figure 3.19: Stages of Meiosis, In Emery's Elements of Medical Genetics, 12th ed.; Churchill Livingstone: Elsevier, 2005.)

chromosomes (19,20). However, the molecular causes underlying age-dependent nondisjunction are still poorly understood (18).

## 10.4 METHODS FOR STUDYING HUMAN CHROMOSOMES

Technical innovations in the past 60 years have revolutionized the study of human chromosomes. Chromosomes are normally visible only during cell division as they become condensed in preparation for orderly division. Therefore, chromosomes can be studied only in cells that are dividing *in vivo* or *in vitro*. Dividing cells are sufficiently common in some tissues *in vivo* to permit the direct study of chromosomes. This is true of meiotic divisions in the testis and embryonic ovary, and of mitotic divisions in the bone marrow, some epithelia, and tumors. However, cell culture methods have greatly extended the range of tissue and cell types from which dividing cells can be obtained *in vitro*. These include blood lymphocytes, fibroblasts from skin and other tissues, and cells from amniotic fluid or chorionic villi. Viable cells can even be obtained for a number of hours after death of an individual or spontaneous abortion of an embryo. It is thus possible to carry out chromosome studies in a wide range of clinical situations.

The introduction of a short-term peripheral blood culture technique provided a reliable way for obtaining human chromosome preparations of good quality for human cytogenetic investigations and for clinical diagnosis (21). In this widely used technique, T-lymphocytes from a small sample of peripheral blood are stimulated to divide in culture with a mitogen, such as phytohemagglutinin. The blood culture is initiated in a suitable culture medium at 37°C, and within 3 days the stimulated lymphocytes provide very large numbers of dividing cells. These are blocked in metaphase by adding a mitotic spindle poison, such as colchicine, to the culture for a few minutes. Treatment of the cells with a hypotonic solution swells the cells and allows spreading of the chromosomes, which are then fixed and mounted on a glass slide. This makes it possible to prepare well-spread, flattened metaphase chromosome preparations on slides suitable for microscopic analysis using chromosome banding methods and molecular cytogenetic techniques.

### 10.4.1 Human Chromosome Identification

In the early days of human cytogenetic investigations, chromosomes were stained with Giemsa or a similar dye, yielding uniform staining along their lengths. Based on these studies, human chromosomes were classified according to their size and morphology (Figures 10-4 and 10-5).

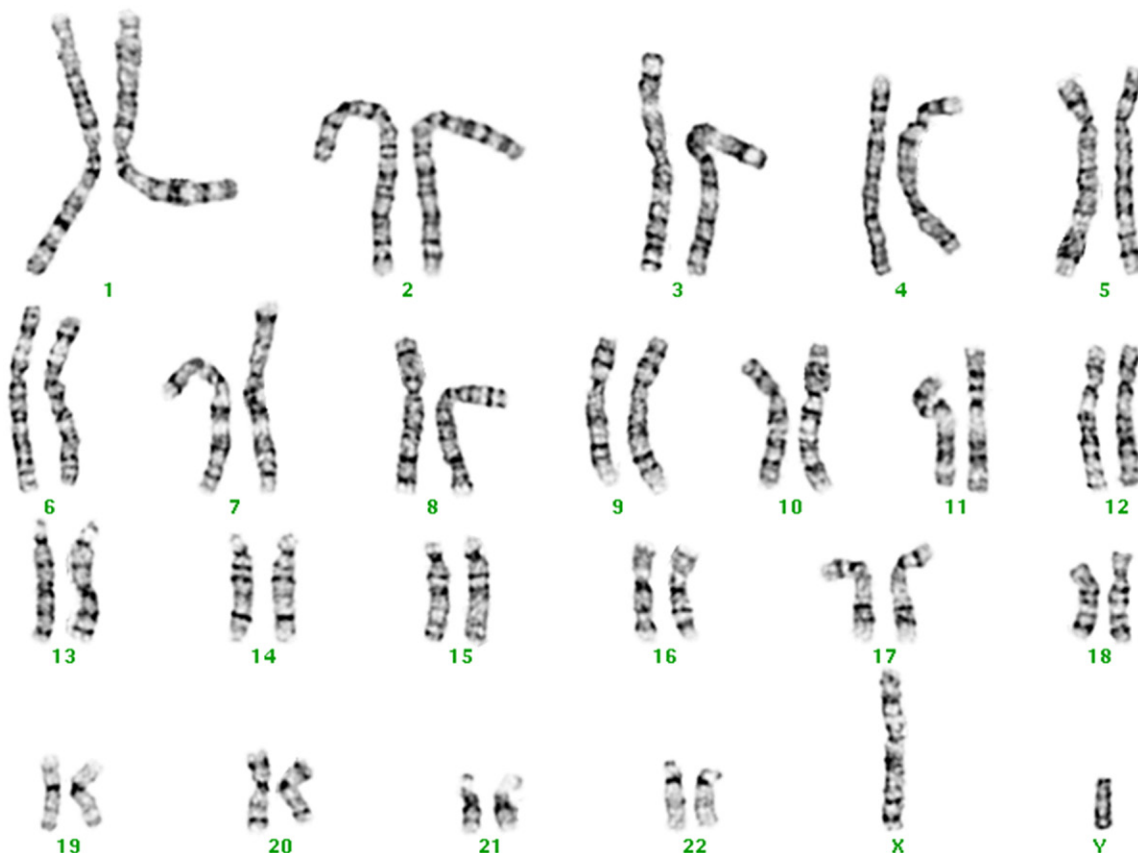

FIGURE 10-4 G-banded karyotype of a male cell.

**FIGURE 10-5** Q-banded karyotype of a male cell.

The primary constriction represents the centromere, the chromosomal locus responsible for proper segregation of chromosomes to daughter cells during cell division. Based on the position of their centromeres, human chromosomes are classified as metacentric, in which the centromere is at or near the middle of the chromosome; submetacentric, in which the centromere is located significantly off center; or acrocentric, in which the centromere is very close to one end. For all categories, the short arm of the chromosome is referred to as “p” for petite, and the long arm as “q.” In addition to the centromere or primary constriction, five pairs of the acrocentric chromosomes (numbers 13, 14, 15, 21, and 22) may exhibit secondary constrictions on their short arms (Figure 10-6). These mark the site of each cluster of ribosomal RNA (rRNA) genes and are called nucleolar organizing regions (NORs) because, at telophase, nucleoli are formed at a subset of these sites that are transcriptionally active. The rRNA genes remain in a moderately extended state at metaphase, reflecting the late shutoff of these genes in prophase and the rapid reinitiation of their transcription after the anaphase separation of sister chromatids. Originally, the chromosomes were assigned to groups A through G according to their general size and position of the centromere (Group A = 1–3, Group B = 4–5, Group C = 6–12 + X, Group D = 13–15, Group E = 16–18, Group F = 19–20, Group G = 21–22 + Y) (Figure 10-4).

### 10.4.2 Chromosome Banding

The conventional (Giemsa) staining without pretreatment does not permit precise identification of each chromosome in the human complement. A major technical innovation in human cytogenetics came in 1970, when Caspersson and colleagues discovered that human chromosomes stained with quinacrine mustard, a fluorescent DNA-binding compound, and examined under ultraviolet light show characteristic variation of fluorescence intensity along the length of each chromosome, producing a banded appearance (22). Each chromosome could then be identified by its characteristic quinacrine (Q)-banding pattern (see Figure 10-5). Subsequently, several techniques were developed that reveal banding patterns reflecting the underlying structural features of chromosomes. Techniques such as Giemsa (G)-banding and reverse (R)-banding produce the full range of bands along each chromosome, allowing identification of individual human chromosomes. Other banding techniques produce much more restricted staining of specific subsets of chromosome bands and include centromere (C)-banding and NOR-banding. A technique that differentially stains the two sister chromatids of a chromosome is also of particular interest. Chromosome banding methods of special interest are discussed in the following paragraphs.

Although Q-banding was the method first employed for human chromosome identification, it is rarely used

**FIGURE 10-6** Partial karyotype of the acrocentric chromosomes from a single cell stained first by Q-banding to identify each chromosome (top panel), and then by the AgNOR technique (bottom panel) to show the sites of the rRNA genes (nucleolar organizing regions).

today for routine chromosome analysis in clinical cytogenetics laboratories, as simpler methods have become available that do not require the use of a fluorescence microscope. A banding pattern that is almost identical to the Q-banding pattern can be produced by treatment of chromosomes with a denaturing agent or a proteolysis enzyme, prior to staining them with Giemsa. In the most consistent and commonly used version of this technique, chromosomes are treated with a dilute solution of trypsin followed by staining with Giemsa (23). The resulting G-banding is the most widely used technique for human chromosome identification in clinical cytogenetics laboratories today (see Figure 10-4). The G-banding patterns are also readily captured and analyzed by computerized karyotyping systems used in clinical cytogenetics laboratories. As an extension of the G-banding technique, methods are now in use for obtaining longer, less condensed prometaphase chromosomes that exhibit twice as many G-bands (about 800 bands per haploid set) as the usual metaphase chromosome preparations (about 400–500 bands per haploid set), providing higher resolution to cytogenetic analysis (24).

Another banding technique of interest, although less commonly used for routine analysis, is one that produces an R-banding pattern. Many approaches have been developed to obtain R-banding, in which the staining intensity of each band is the reverse of that seen with Q- or G-banding. A commonly used method to generate R-bands is to subject chromosome preparations to moderate heat (~85 °C in the presence of high salt) before staining them with Giemsa. R-banding of the highest resolution is obtained by a combination of the fluorescent dye chromomycin A3, which emits fluorescence most strongly in the R-bands, and distamycin A, which quenches fluorescence in G-bands. An alternative R-banding technique that also provides some insight into the mechanism of chromosome banding is based on the differential replication timing of chromosome bands (25). In this technique, growing cells are exposed to the thymidine analog bromodeoxyuridine (BrdU) during the S phase of the cell

cycle and examined following staining with the fluorochrome acridine orange. Cells that incorporate BrdU into their DNA at the late stage of the S phase are selected for observation. With acridine orange staining, the BrdU-containing chromosomal regions appear dull (G- or Q-bands), whereas the early-replicating regions that have incorporated thymidine fluoresce brightly, giving a reverse or R-banding pattern (Figure 10-7). Thus, the R-bands on chromosomes represent regions that replicate their DNA early in the synthetic (S) phase of the cell cycle. The inactivated, late-replicating X chromosome in females (see later) is also stained differentially (dull) from the active X chromosome following this replication banding protocol (see Figure 10-7).

The banding pattern of each chromosome is specific and can be shown in the form of a continuous series of bands. A standardized map of banded chromosomes is known as an “Idiogram.” Subsequent to the development of banded human karyotypes, a standardized nomenclature for the bands was established by the International Standing Committee on Human Cytogenetic Nomenclature. Updated regularly, this standardized system allows the precise description of chromosome abnormalities (26).

The C-banding method selectively stains the areas located around the centromeres of all chromosomes and on the distal long arm of the Y chromosome (27). The largest C-bands usually occur on chromosomes 1, 9, and 16 and the Y in regions that contain highly repetitive, nontranscribed DNA. To elicit C-bands, metaphase chromosome preparations are treated with sodium hydroxide or barium hydroxide followed by Giemsa staining (Figure 10-8). The size of the C-band on a given chromosome is usually constant in all the cells of an individual but is highly variable from person to person, reflecting variations in the amount of heterochromatic DNA present at the centromeric regions. Such C-band heteromorphisms on chromosomes are transmitted from parent to offspring as simple Mendelian dominant traits. These variations in chromosome morphology are not associated

**FIGURE 10-7** R-banded karyotype of a female cell following incorporation of BrdU into the late-replicating regions of the chromosome.

**FIGURE 10-8** C-banded karyotype of a male cell.

with any known phenotypic effects and are referred to as chromosome polymorphisms. They are, however, useful as heritable chromosome markers in various clinical and epidemiologic studies of chromosome abnormalities.

Silver NOR (AgNOR) staining uses a silver nitrate solution to selectively stain the sites of transcriptionally

active rRNA genes, which are located in the stalk regions on the short arms of human acrocentric chromosomes (28). Silver staining regions are usually present on 6–8 of the 10 acrocentric chromosomes, 13, 14, 15, 21, and 22 (Figure 10-6), although they may be seen on as few as 3 or as many as all 10 of these chromosomes. The sizes of the AgNORs are highly variable in the human population, although the size of each AgNOR in the cells of one individual is quite consistent and usually remains unchanged from one generation to the next. AgNOR staining is useful in characterizing rearrangements involving human acrocentric chromosomes. The mechanism of AgNOR staining is based on the oxidation of nucleolar nonhistone proteins with silver nitrate, by which Ag is reduced to black native silver. Interestingly, the acrocentric chromosomes show association of their satellite stalk regions even in metaphase chromosome preparations, reflecting the functional association of these sites in the formation of the nucleolus in the interphase nucleus. This association of the NORs is considered to be a factor responsible for the high incidence of Robertsonian translocations involving the short arms of acrocentric chromosomes.

Sister chromatid exchange (SCE) is an extension of the replication banding technique using BrdU incorporation to produce differential staining of the two sister chromatids of the metaphase chromosome. This requires incorporation of the thymidine (T) analog BrdU (B) into DNA during two successive rounds of DNA replication. At the end of the first round of DNA replication, the

two newly synthesized strands of DNA in the double-stranded helix will contain BrdU, but not the two template strands. At the end of the second round of DNA replication, two new double-stranded helices will be produced, of which one will have BrdU incorporated on both strands (BB) and the other of which will have BrdU substitution in only one strand of the DNA double helix (TB). When the chromosomes containing singly (TB) and doubly (BB) substituted chromatids are stained with the DNA-binding fluorochrome Hoechst 33258, and exposed to ultraviolet light, they show differential sister chromatid staining, with the bifilarly substituted chromatid exhibiting paler fluorescence (29). Staining of these BrdU-incorporated chromosomes with Giemsa produces darkly stained (TB) and lightly stained (BB) sister chromatids (30) (Figure 10-9). Therefore, exchanges of material between sister chromatids are readily visible at high resolution following this staining protocol. The differential sister chromatid staining observed following the SCE protocol is a remarkable cytologic demonstration of the semiconservative replication of DNA. It also demonstrates that each chromosome is composed of a single very long duplex of DNA. Further, it shows that exchanges between the two sister chromatids take place in somatic cells that could potentially have mutagenic effects. SCE is used to diagnose diseases associated with chromosomal instability in clinical cytogenetics laboratories. For example, SCE analysis is a diagnostic test for Bloom syndrome, a rare autosomal recessive disease caused by mutations in a DNA helicase of the RecQ family that catalyze the unwinding of duplex nucleic acid molecules (31). It is characterized by growth deficiency, predisposition to neoplasia, and chromosomal instability in somatic cells. The frequency of spontaneous SCEs

in cells from patients with Bloom syndrome is markedly increased. SCE analysis is also used to monitor the effects of potentially mutagenic or carcinogenic agents that enhance the rate of SCEs.

### 10.4.3 Chromosome Banding Reveals Genome Sequence Organization

Quinacrine associates directly with DNA by intercalating between base pairs. Although quinacrine binds equally well to DNA of any base composition, its fluorescence is enhanced in regions containing uninterrupted runs of AT base pairs, and is quenched in regions with more frequent GC base pairs. In the Q-banding pattern of human chromosomes (see Figure 10-5), the intensity of fluorescence is generally proportional to the AT-richness of the DNA (32). However, the highly AT-rich satellite DNA that is concentrated at the C-bands of chromosomes 1, 9, and 16 has interspersed GC base pairs and usually fails to show bright Q-banding. That on the Y, in contrast, has no such GC pairs and is intensely fluorescent. Thus Q-banding is related to both base composition and base interspersion that result in the differential fluorescence or quenching of signals produced by the fluorescent dye. DNA-protein interactions may also be important in the generation of Q-bands.

G-banding is produced most commonly by treatment of chromosomal preparations with the proteolytic enzyme trypsin. Giemsa stains DNA primarily by intercalating between adjacent base pairs in double-stranded regions. G-bands result from the degradation of chromosomal proteins by trypsin, which modifies the interaction of chromosomal DNA with the Giemsa dyes. Since the fixative used in standard chromosome preparation methods, methanol:acetic acid (3:1), removes some of the histone proteins, it is the degradation of the nonhistone proteins that appears to be critical for the production of G-bands. The DNA-protein interactions at the G-band-positive regions apparently render these sites resistant to denaturation by the enzyme.

The commonly used method to generate R-bands is to subject chromosome preparations to moderate heat (~85°C in the presence of high salt) before staining them with Giemsa. The heat pretreatment is thought to selectively denature the more AT-rich DNA sequences, which have a lower thermal stability than GC base pairs, and to result in altered DNA structure on renaturation. Therefore, after chromosomes are exposed to moderate heat, Giemsa stains the unaffected GC-rich double-stranded DNA regions, producing R-banding. R-bands can also be produced by the replication banding technique, which demonstrates that R-band-positive regions contain early-replicating DNA. It also follows that G-band- and Q-band-positive regions contain AT-rich DNA that replicates relatively late in the cell cycle (32).

C-band-positive regions have been found by *in situ* hybridization and DNA sequencing to consist of

**FIGURE 10-9** SCEs shown in Chinese hamster ovary cells.

$\alpha$ -satellite (discussed later) sequences at the centromeres of human chromosomes and of different families of simple sequence satellite DNAs at the large pericentromeric C-band blocks on chromosomes 1, 9, and 16 and distal Yq. Analyses of the completed human genome sequence have defined further families of repetitive DNA (33), but these have not yet been associated with functional or structural landmarks of chromosomes. In contrast, recent studies employing *in situ* hybridization as well as *in silico* analyses of the genome sequence have revealed that the human genome also includes highly homologous duplications of DNA ranging in size from 1 to more than 500 kb. These repeats, called segmental duplications, are located mainly in the pericentromeric and subtelomeric regions of chromosomes, although they are also present as interspersed repeats along the length of the chromosome (33,34). While some of these segmental duplications are known to predispose to genomic deletions and duplications, their significance for chromosomal function is otherwise unknown. A comparison of the characteristics of Q-/G-, R-, and C-bands is presented in Table 10-1.

Also related to simple sequences are chromosomal regions called fragile sites that remain stretched at metaphase after various treatments that limit DNA replication (35). Fragile sites are classified as rare (inherited) or common (constitutional) and are further subdivided according to the conditions under which they are induced (e.g. folate or amphotericin sensitive). Several fragile sites have now been cloned and sequenced. These studies have shown that the expression of rare, inherited fragile sites is associated with repeat expansions (35). The first folate-sensitive rare fragile site to be characterized was the one associated with the fragile X syndrome (FMR1), which was shown to result from the expansion and methylation of a CGG trinucleotide repeat in the 5' UTR of the *FMR1* gene. Other folate-sensitive fragile sites characterized thus far also result from expansion of trinucleotide repeats (36). A distamycin-sensitive rare fragile site on chromosome 16 has been shown to involve the expansion of a 33 bp AT-rich minisatellite (36). In contrast,

sequencing of constitutional fragile sites has not revealed any characteristic DNA sequences at these sites (37).

#### 10.4.4 Molecular Cytogenetics

The gap between light microscope resolution of chromosome structure and the gene was bridged by the introduction of several molecular cytogenetic techniques. Fluorescence *in situ* hybridization (FISH) involves hybridizing a fluorescently labeled single-stranded DNA probe to denatured chromosomal DNA on a microscope slide preparation of metaphase chromosomes and/or interphase nuclei prepared from the patient's sample. After overnight hybridization, the slide is washed and counterstained with a nucleic acid dye (e.g. DAPI), allowing the region where hybridization has occurred to be visualized using a fluorescent microscope (38). FISH is now widely used for clinical diagnostic purposes. There are different types of FISH probes, including locus-specific probes, centromeric probes (CEPs), and whole-chromosome paint probes. Locus-specific probes are specific for a particular single locus. They are particularly useful for identifying subtle submicroscopic deletions and duplications (Figure 10-10). CEPs are specific for unique repetitive DNA sequences (e.g.  $\alpha$ -satellite sequences) in the centromere of a specific chromosome. They are suitable for making a rapid diagnosis of one of the common aneuploidy syndromes (trisomies 13, 18, and 21, and sex chromosome aneuploidies) using nondividing interphase nuclei. This is particularly useful in a prenatal setting using amniotic fluid or chorionic villi samples (Figure 10-11). Whole-chromosome paint probes consist of a cocktail of probes obtained from different regions of a particular chromosome. When this cocktail mixture is used in a single hybridization, the entire relevant chromosome fluoresces (is "painted") (Figure 10-12). Whole-chromosome paints are useful for characterizing complex chromosomal rearrangements, and for identifying the origin of additional chromosomal material such as small marker or ring chromosomes.

**TABLE 10-1** Characteristics of Chromosome Bands

Characteristic	Q- or G-Bands	R-Bands	C-Bands
Location	Chromosome arms	Chromosome arms	Centromeres, distal Yq
Type of DNA sequence	Repetitive, some unique	Unique, some repetitive	Highly repetitive satellite
Base composition	AT-rich	GC-rich	AT-rich, some GC-rich
5-methylcytosine content	Low	Moderate	High
Type of chromatin	Heterochromatin	Euchromatin	Heterochromatin
Replication	Mid to late S phase	Early S phase	Late S phase
Transcription	Low	High	Absent
Gene density	Low	High	Absent
CpG-rich islands	Few	Many	Absent
Repeats	LINE-rich	SINE-rich	—
Acetylated histones	Low	High	Absent

**FIGURE 10-11** Interphase FISH analysis in a patient with trisomy of chromosome 18. Note the three copies of the chromosome 18 centromeric probe (CEP 18) labeled in aqua.

**FIGURE 10-12** Metaphase FISH analysis using chromosome 5 paint probe.

FISH using locus-specific probes has been extremely useful in the detection of “microdeletion syndromes” resulting from deletions of multiple contiguous genes. These are subtle submicroscopic deletions that are below the resolution of the routine G-banded chromosome analysis. Also, two-color and three-color FISH applications are routinely used to diagnose specific deletions, duplications, or other rearrangements, both in metaphase chromosomes and in interphase nuclei. Use of FISH usually requires that the patient either exhibits features consistent with a well-defined syndrome with known chromosomal etiology or demonstrates an abnormal karyotype. This is because single FISH probes reveal rearrangements only of the segments being interrogated, but do not provide information about the rest of the genome. Another limitation of FISH is the number of probes that can be applied in a simultaneous assay. FISH techniques have been developed utilizing pools of whole-chromosome paint probes for every chromosome

to provide a multicolor human karyotype in which each pair of homologous chromosomes can be identified on the basis of its unique color when studied using special computer-based image analysis software (Spectral karyotyping and M-FISH) (39).

One type of FISH that has the potential to reveal chromosomal imbalances across the genome is comparative genomic hybridization (CGH). In CGH, DNA specimens from patient and normal control are differentially labeled with two different fluorescent dyes and hybridized to normal metaphase chromosome spreads. Difference between the fluorescent intensities of the two dyes along the length of any given chromosome will reveal gains and losses of genomic segments (40). The limitations of this technology include many of the same limitations of G-banded chromosome analysis. Thus, like G-bands, the resolution of CGH is limited to that of metaphase chromosomes, which is approximately 5 Mb for most clinical applications (39).

The latest addition to molecular cytogenetic techniques is array CGH, where CGH is applied to an array of DNA targets (probes) each representing a part of the human genome and fixed to a solid support (usually a glass slide). Like CGH, array CGH directly compares DNA content between two differentially labeled DNA specimens (a test or patient and a reference or normal control), which are labeled and co-hybridized onto the array. Arrays have been constructed with a variety of DNA targets, ranging from bacterial artificial chromosomes (BACs) which are 80–250 kb long to oligonucleotides (oligos), which are 25–80 bp long (41–43). Following hybridization and washing to remove unbound DNA, the array is scanned and analyzed using special computer software to measure the relative ratios of fluorescence of the two dyes and detect gains/losses of genomic regions represented on the array (Figure 10-13). The resolution of array CGH is dependent on the type of probes used (BACs or oligos) and the distance between them. In the past few years, high-resolution whole-genome coverage array CGH platforms have been increasingly used in clinical molecular cytogenetics labs. These provide a relatively quick method to scan the entire genome for gains and/or losses with significantly high resolution and greater clinical abnormality yield than was previously possible. This led to the identification of novel genomic disorders in patients with autism spectrum disorders, developmental delay, mental retardation, and/or multiple congenital anomalies (44).

## 10.5 FUNCTIONAL ORGANIZATION OF CHROMOSOMES

Chromatin is classified into euchromatin and heterochromatin. Euchromatin consists of active genes; however, not all genes in euchromatic regions are active at any given time. Therefore, location in euchromatin is currently thought to be necessary but not sufficient for gene activity.

Euchromatin is dispersed in the interphase nucleus and replicates its DNA early in the S phase of the cell cycle. Heterochromatin consists predominantly of inactive genetic material, replicates its DNA late in the S phase, and is condensed in the interphase nucleus. Heterochromatin is further classified into constitutive heterochromatin and facultative heterochromatin. Constitutive heterochromatin consists of highly repetitious simple-sequence DNA, remains transcriptionally inactive, and is located at specific regions of the chromosomes such as the centromere and the distal long arm of the human Y chromosome. Facultative heterochromatin also remains condensed in the interphase nucleus, replicates its DNA late in the S phase, and is largely transcriptionally inactive. However, it is not inactive permanently, does not consist exclusively of repetitious DNA, and can become transcriptionally active. The inactive X chromosome in the human female is a good example of facultative heterochromatin. However, location in facultative heterochromatin does not exclude transcription altogether, as several genes on the inactive X chromosome are expressed (see later). As already noted, the R-band-positive regions of human chromosomes have characteristics of euchromatin in that they replicate their DNA in early S phase and have high transcriptional activity due in part to high gene density (see Table 10-1). The G-band-positive regions, on the other hand, are more heterochromatic as they replicate their DNA in late S phase and are low in transcriptional activity associated with low gene density. Integration of the whole human genome sequence with the cytogenetic map shows a lower density of genes in G-positive bands (45). The C-band-positive regions consist of constitutive heterochromatin with no known functional genes. The facultative heterochromatin of the inactive X chromosome replicates its DNA in late S phase, and forms the condensed Barr body in the interphase nucleus. Consequently, there is a general relationship of functional properties (time of replication during the S phase and transcriptional status or gene density) with chromosome band classes characterized by differential condensation and staining characteristics (46).

Recent investigations have provided insights into the molecular organization of two specialized structures on chromosomes, the centromere and the telomere, which are of particular interest and are summarized below.

### 10.5.1 The Centromere

As already noted, each chromosome has a primary constriction, the centromere, where the sister chromatids of a replicated chromosome are held together until the anaphase stage of cell division. A subdomain of the centromere is the kinetochore, a protein–DNA complex that serves as the attachment site for the spindle fibers essential for chromosome movement and segregation during mitosis and meiosis. The structure of the centromere has been a focus of molecular cytogenetic investigations in recent years. The best characterized eukaryotic

**FIGURE 10-13** Oligo-array CGH analysis in a patient with *NF1* gene deletion on chromosome 17 band q11.2. (A) Whole chromosome 17. (B) Deleted region. Shaded areas show the deleted region.

centromere is that of the budding yeast *Saccharomyces cerevisiae*. In this organism, a short sequence of about 125 bp specifies the centromere of each of the chromosomes. The nucleotide sequence and organization of this centromere DNA is conserved among the different chromosomes in the budding yeast. The search for a similar specific sequence in the larger and more complex centromeres of higher eukaryotes has not been successful. Rather, the centromeres in these organisms consist of large arrays of repeated  $\alpha$ -satellite DNA sequences. In human centromeres, the arrays consist of tandem, head-to-tail repeats of a 171 bp monomer that is further organized into higher order repeats (47). The centromeric chromatin of human chromosomes spans from 0.1 to 4.0 Mb. The sequence of the basic 171 bp unit is sufficiently divergent among human chromosomes that, with very few exceptions, centromere-specific  $\alpha$ -satellite DNA probes can generate fluorescent signals on specific chromosomes in a FISH assay. This is useful from a practical standpoint for identifying and determining the copy number for specific human chromosomes in interphase cells.

Several lines of evidence implicate a critical role for  $\alpha$ -satellite DNA in centromere function. Although there are other repeated sequences in the centromeric heterochromatin,  $\alpha$ -satellite is the only one localized to the centromeres of all normal human chromosomes. Moreover, studies have shown that human artificial chromosome constructs containing  $\alpha$ -satellite DNA are able to form functional centromeres (48). However, independent evidence from rearranged chromosomes suggests that the presence of  $\alpha$ -satellite DNA alone is not sufficient for the formation of an active centromere. Many cases of rearranged human chromosomes containing two centromeric regions have been identified. A true dicentric chromosome with two primary constrictions would be unstable during cell division as spindle fiber attachment occurs independently at the two centromeres, if these are sufficiently far apart. The two centromeres on a single chromatid could then be pulled toward opposite poles of the spindle, breaking the chromosome. However, many dicentric chromosomes with two blocks of  $\alpha$ -satellite DNA and C-band regions are stable and show only one primary constriction, indicating that only one of the two centromeres is active. Such stable dicentric chromosomes, referred to as pseudodicentrics, indicate that the presence of  $\alpha$ -satellite DNA alone is not sufficient for the formation of an active centromere. In addition, several human marker chromosomes have been characterized that originate from normal human chromosomes but lack  $\alpha$ -satellite DNA sequences. These functional centromeres lacking  $\alpha$ -satellite DNA are called neocentromeres (49). As these chromosomes are mitotically stable, presence of  $\alpha$ -satellite DNA is not an absolute requirement for functional centromeres. Thus, although normal human centromeres are composed of  $\alpha$ -satellite DNA, it appears to be neither necessary nor sufficient for centromere formation.

Recent investigations have identified several proteins associated with centromeres that have contributed to our understanding of centromere structure and function (50,51). A group of these proteins are constitutively associated with centromeres while others are associated with centromeres only during a part of the cell cycle and are involved in chromosome movement during cell division. The major constitutive centromere proteins identified are CENP-A, CENP-B, and CENP-C. The location of these proteins at centromeres has been determined by immunofluorescence microscopy using antibodies specific for these proteins. CENP-A is a 17 kDa histone H3-like protein that participates in producing centromere-specific nucleosomes (in place of histone H3) and altered chromatin structure. CENP-A is detected at all functional centromeres, including the neocentromeres. CENP-B is an 80 kDa protein that binds to a specific 17 bp sequence, the CENP-B box, in  $\alpha$ -satellite DNA and is found, as expected, even at the inactive centromere of pseudodicentric chromosomes. CENP-C, a 140 kDa protein, is also found at active centromeres, where it is located in the proteinaceous kinetochore. CENP-C shares homology with a domain of the Mif2 protein of yeast that is essential for normal chromosome segregation. In addition to the CENP-A, -B, and -C proteins that associate with centromeres constitutively, many more that associate transiently during cell division have been identified. An example of the latter class of proteins is CENP-E, a 275 kDa kinesin-related protein that is associated with centromeres and mitotic spindle during mitosis and plays a role in chromosome movement.

## 10.5.2 The Telomere

Telomeres are special DNA-protein structures that are present at the ends of linear chromosomes and prevent fusion of chromosome ends and maintain chromosome integrity. The concept of the telomere was developed from early genetic and cytologic observations that the broken ends of chromosomes are unstable and often fuse with other broken ends. Molecular techniques have now shown that telomeres in eukaryotes exist in a DNA-protein complex consisting of tandem repeats of a simple sequence and a number of proteins. In humans and other vertebrates, the sequence of the basic repeat is 5'-TTAGGG-3' on one strand of the DNA and 5'-CCCTAA-3' on the complementary strand. The G-rich strand runs 5'-3' toward the end of the chromosome, with a short, single-stranded, G-rich overhang (52,53). The human telomeric sequence typically spans about 2–50 kb and is replicated by its own polymerase, called telomerase. In the absence of telomerase, each round of DNA replication leaves 50–200 bp of DNA unreplicated at the 3' end as the DNA replication machinery works only in the 5'-3' direction and requires an RNA primer. This would result in loss of sequences from the ends of chromosomes, ultimately leading to loss of genetic material.

Telomerase is a ribonucleoprotein complex that includes a reverse transcriptase and a short RNA molecule that provides the template for synthesizing the telomeric sequences. By copying the RNA template, telomerase extends the G-rich telomeric DNA strand running 5'–3' toward the distal end of the chromosome. The complementary strand is then synthesized by the cellular DNA replication machinery through lagging strand synthesis. Telomere-associated proteins regulate telomerase activity so that the length of telomere repeat tract is maintained at a level required for maintaining functional telomeres (53,54). Telomerase is present in early embryonic cells and in the majority of immortalized cells, but not in most somatic cells. As a result, somatic cells, but not cancer cells, lose telomeric sequences with each division, leading to dysfunctional telomeres and excessive chromosomal instability. Telomerase activity is therefore considered to be a critical factor contributing to the finite life span of most somatic cells and indefinite growth potential of cancer cells. Studies have shown that telomere sequences can be added to the ends of chromosomes with terminal deletions, thus stabilizing these broken ends. Healing of broken ends can occur through two general pathways, ensuring the acquisition of a new telomeric cap and stabilizing the deleted chromosome. First, direct addition of telomeric sequences onto the broken end can be achieved through a telomerase-mediated *de novo* telomere addition (55,56) or a telomerase-independent recombination-based mechanism (57,58). Second, telomeres can also be retrieved from another location through a mechanism called telomere capture, in which subtelomeres and/or pan-telomeres from another chromosome are translocated at the broken end of the deleted chromosome (59,60).

Adjacent to the human terminal (TTAGGG) $_n$  repeat is a complex region of segmentally duplicated DNA tracts generally referred to as subtelomeric repeat DNA or telomere-associated repeats (TARs). This class of low-copy repeat DNA is characterized by very high sequence similarity (>90%) between duplicated tracts, and variably sized but often very large duplicated segments. Some of the segmental duplications are unique to TARs, some are shared with a subset of pericentromeric repeat regions, and some are shared with one or several interstitial chromosomal loci. These TARs range in size from 100 to 300kb, and just proximal to these regions the unique subtelomeric sequences are encountered (61).

## 10.6 SEX CHROMOSOMES AND SEX DETERMINATION

Sex chromosomes of the human chromosome complement are of special interest, as they determine sex of the human embryo. Also, the sex chromosome pair, the X and Y, is heteromorphic (different in size and morphology) in humans. The Y chromosome is significantly smaller than the X chromosome and contains a

large block of heterochromatin on its q arm comprising noncoding repetitive DNA. This leaves only a short segment of chromosome capable of carrying functional genes. The finding of heteromorphic sex chromosomes in humans, an XX pair in females and an XY pair in males, suggested a chromosomal basis for sex determination in the early twentieth century. However, the dominant role of the Y chromosome in male sex determination became evident only in 1959, when cytogenetic studies showed that individuals with a complete set of autosomes and a single X chromosome developed as females, whereas individuals with two X chromosomes and a Y chromosome developed as males (62,63). We now know that individuals with as many as four X chromosomes and a Y also develop as males. The number of X chromosomes or its ratio to the number of autosomes is not important for human male sex determination. The Y chromosome thus carries a dominant determinant for testis development.

Unlike autosomal pairs of chromosomes, the heteromorphic X and Y are not completely homologous. There are two regions of complete homology between the X and Y chromosomes that reside at the distal ends of their short and long arms, covering approximately 2600 and 320kb of DNA, respectively (64). The X and Y chromosomes pair and cross over in these regions during prophase I. This appears to be essential for correct segregation of the sex chromosomes. As a result of this crossing over, female offspring of males can inherit DNA sequences from the Y chromosome distal to the point of exchange and vice versa. Thus genetic markers in this region of pairing and exchange between the X and Y segregate independently of sexual phenotype, and hence this region is called the pseudoautosomal region.

### 10.6.1 The Y Chromosome and Sex Determination

Identification of the testis-determining factor (TDF) on the human Y chromosome has been of much interest since the role of the Y in male sex determination was established. Early cytogenetic investigations in individuals with structurally abnormal Y chromosomes showed that the TDF resided on the p arm of Y. The isolation and molecular characterization of this gene was made possible by studies of a naturally occurring sex-reversed condition, the XX male. Cytogenetic and molecular investigations of XX males showed that the majority of them resulted from an unequal exchange between X and Y, such that the TDF is transferred from the Y to the X chromosome. By identifying the minimal region of Y necessary for male determination from independent XX males, and searching this region for candidate genes, the SRY (sex-determining region on Y) gene was identified. Later studies confirmed that SRY is the long-sought TDF (65). SRY, which resides just proximal to the pseudoautosomal region on the p arm of the Y chromosome, encodes a protein of 240 amino acids, which is capable of

sequence-specific binding to DNA using a motif known as the HMG box (66,67). This motif is found in several classes of DNA-binding proteins, including several that are known to be transcription factors. Unlike other transcription factors, the SRY protein does not contain any other recognizable motifs, and this has led to the hypothesis that it functions partly as scaffold protein in chromatin (68). SRY induces the differentiation of Sertoli cells in the developing gonad. Sertoli cells produce anti-Müllerian hormone, which causes regression of the female internal genitalia; they also induce Leydig cells to secrete the androgens necessary for the development of male internal and external genitalia (65). Any genetic or environmental factor that prevents testis differentiation in 46,XY embryos leads to the development of a sex-reversed XY female. Recent molecular dissection of other conditions that result in sex reversal has allowed the identification of some of the other genes involved in the sex-determining pathway (69–71). Not surprisingly, many of these are autosomal and not sex-linked genes.

### 10.6.2 The X Chromosome

The heteromorphic nature of the sex chromosome pair in humans immediately raises the question of dosage difference for X-linked genes in the human male and female. The answer to this question was provided by observations on the behavior of the two X chromosomes and the expression patterns of X-linked genes in human and other mammalian females. These findings indicated that there were differences in the functional organization of the two X chromosomes in mammalian females. Early cytologic studies demonstrated that a sex chromatin body (called the Barr body) was present in female interphase cells, but not in male cells. Moreover, the amount of certain X-linked gene products, such as the enzyme glucose-6-phosphate dehydrogenase, was no different in individuals with one, two, or even more X chromosomes. Also, studies on the timing of DNA replication in diploid cells indicated that the DNA in one X chromosome replicated in synchrony with the DNA of the autosomes, while that of any additional X chromosomes replicated late in the S phase. Thus, the number of Barr bodies equals the number of late-replicating X chromosomes.

Based on the observation that female mice heterozygous for X-linked genes show mosaicism for the expression of these genes, Lyon in 1961 proposed the single active X hypothesis (72), which offers an explanation for the gender-specific behavior of the X chromosome and X-linked genes. According to this hypothesis, commonly referred to as the Lyon hypothesis, the somatic cells of all mammals undergo a process of chromosome differentiation early in embryogenesis that leaves a single active X chromosome per cell. All additional X chromosomes are inactivated by a process that renders them heterochromatic and capable of forming a Barr body. Thus diploid somatic cells of individuals with three X chromosomes

have two Barr bodies, while those of individuals with four X chromosomes have three Barr bodies. The initial choice for inactivation of an X is random in a normal female. However, this differentiation is fixed, so that all the descendants of a cell in which the maternal X was inactivated initially will have the maternal X in the inactive state, while the descendants of a cell in which the paternal X was inactivated will have that X in the inactive state. Every XX individual is thus a genetic mosaic consisting of cells in which the maternal X is active and cells in which the paternal X is active.

The phenomenon of X chromosome inactivation has been a subject of much interest and investigation in mammalian biology. This interest in X-inactivation derives from the fact that it is a relatively unique epigenetic process of gene regulation at the level of the chromosome. It is epigenetic because the inactivated X chromosome does not undergo any permanent changes in its DNA sequence and can be reactivated, as it is in female germ cells. Genes from the inactive X chromosome can also be reactivated experimentally in cultured cells (73). Further, attention has been focused on X-inactivation as means of understanding broader aspects of chromatin, specifically the structure and function of facultative heterochromatin. Finally, the burden of human X-linked diseases and X chromosome abnormalities has generated an interest in X-inactivation for a better understanding of the pathogenesis and ultimately the treatment of these conditions.

Investigations in the last two decades have provided insights into the molecular mechanism of X chromosome inactivation. It is now clear that DNA methylation plays a key role in maintaining the X in the inactive state. Studies of several genes have shown that cytosine residues in cytosine-guanine dinucleotides (CpG) in their 5' promoter regions are methylated when they reside on an inactive X, and unmethylated on an active X (74). The binding of proteins that specifically bind methylated DNA and inhibit transcription could account for the transcriptional silencing of genes on the inactivated X. Studies employing immunofluorescent labeling of human metaphase chromosomes with antibodies specific for acetylated isoforms of nucleosome core histones have shown that the inactive X chromosome is hypoacetylated, linking methylation and histone acetylation in the control of gene expression from the inactive X (75,76). Examination of histone H4 acetylation status at the individual gene level has also shown hypoacetylation in the promoter regions of X-inactivated genes (77). Hypermethylation of DNA, hypoacetylation of histones, and methylation of histone H3 at lysine 9 (H3-mK9) are features common to all heterochromatin (78). Initiation of X-inactivation, which must also include counting the number of Xs in a cell and the spreading of inactivation along the X, is still not completely understood. However, these early events in X-inactivation are dependent on the X-inactivation center (XIC), a complex specialized

control locus located in the proximal q arm of the human X chromosome. The XIC is required for the initiation of X-inactivation and is invariably present on all X chromosomes that undergo inactivation, including those with structural rearrangements. A search for candidate genes mapping to the XIC region led to identification of the *XIST* (X-inactive specific transcript) gene. The *XIST* gene, expressed exclusively from the inactive X and not from the active X, is located at the XIC (79). The product of *XIST* is a large noncoding RNA molecule that stays associated with the inactive X (80). Transgenic and knockout experiments indicate that *XIST* is necessary and sufficient for initiating X-inactivation (81–83). While the precise mechanism(s) of X chromosome inactivation remain to be revealed, the process is generally described in four stages: recognition of the number of X chromosomes (also called “counting”); initiation early in development; promulgation whereby the initial signal is spread to the rest of the chromosome; and maintenance of the inactivating signal through successive cell divisions (84).

It is now well established that not all genes on the X chromosome are subject to X-inactivation. Early studies showed that the genes for the Xg blood group and for the enzyme steroid sulfatase (deficiency of which causes X-linked ichthyosis) escape X-inactivation (64,84). More recent studies evaluating an estimated 95% of X-linked genes assayable in cell culture systems show that about 15% of these genes escape inactivation, and an additional 10% show variable levels of expression from the inactive X chromosome (80,85). The majority of the genes that escape inactivation are located on the p arm of the X chromosome, but they are also present on the q arm and are interspersed with genes that undergo inactivation. As expected, the genes in the pseudoautosomal regions escape X-inactivation; these have homologs on the Y chromosome, and dosage compensation is not a requirement for these genes. However, there are genes on the X that escape X-inactivation for which there is no functional homolog on the Y, thus resulting in an increased dose in the female. These differences between the X and Y reflect the evolutionary history of the sex chromosomes. It is thought that the heteromorphic sex chromosomes of today evolved from a homomorphic autosome-like pair with progressive loss of genes from the Y and incorporation of the corresponding genes on the X into the X-inactivation system. The genes that escape inactivation on the X may be essential for normal female development in two doses or they may have simply failed to be incorporated into the X-inactivation system with no adverse consequences. The abnormal development associated with X chromosome aneuploidy is most readily explained by dosage inequities in these genes that escape inactivation. Identification of the specific genes involved in these diseases is, therefore, of great interest and is a focus of ongoing investigations.

## 10.7 UNIPARENTAL DISOMY AND IMPRINTING

It has been appreciated for some time that one paternal and one maternal set of chromosomes are required for the normal development of the embryo. In rare cases, a pregnancy arises in which an ovum undergoes some degree of embryonic development by a process of gynogenesis or androgenesis; that is, the cells are solely of maternal origin (gynogenesis) or of paternal origin (androgenesis). Ovarian teratomas appear to be the result of gynogenetic development of ova that have not undergone the second meiotic division. The cells are thus diploid and XX. In contrast, some pregnancies, which terminate in spontaneous abortion, are associated with the presence of a hydatidiform mole, an abnormal development of extra-embryonic tissue. Many of these moles are diploid and XX (or rarely, XY), with both sets of chromosomes of paternal origin. They may arise as a result of fertilization of an anucleated ovum by two sperms.

One of the most interesting novel concepts to emerge from these and other experimental studies in the mouse is that of genomic imprinting, which provides an explanation for the abnormal development of gynogenetic and androgenetic embryos. Genomic imprinting refers to a process by which maternal and paternal alleles of specific genes or chromosomal regions are differentially marked during gametogenesis such that they are expressed differently in the embryo (86). One allele of the imprinted gene is usually active, while the other is inactive. Thus, the paternal and maternal copies are not functionally equal for all genes, and therefore both a maternal copy and a paternal copy are required for normal development. Like X chromosome inactivation, genomic imprinting is also an epigenetic phenomenon in that the imprinted gene does not undergo any permanent change and the imprint is reversible. Thus a female who begins life with a maternally and paternally imprinted allele at a locus will produce gametes that exhibit only maternal imprint even on her own paternal chromosome. Similarly, males produce only gametes with the male-specific imprint. In other words, during gametogenesis the parental imprint is erased and reset in a sex-specific manner. As in X chromosome inactivation, DNA methylation is a mediator of the maintenance of the imprint in the somatic cells.

Imprinting is known to affect only a small number of genes and chromosomal regions in the human genome. Imprinting thus differs from X-inactivation in that it does not affect a whole or most of a chromosome. Moreover, even within an imprinted chromosomal region, individual genes located within a few hundred kilobases of DNA may show differential imprinting. As a result, one gene may be inactive on the maternal chromosome and active on the paternal chromosome while a neighboring gene exhibits the opposite imprinting, being active on the maternal chromosome and inactive on the paternal chromosome. Imprinting also shows tissue-specific variation

for certain genes. Thus, the Angelman syndrome gene, UBE3A, on chromosome 15 is expressed from both chromosomes (biallelic expression) in somatic cells but is expressed only from the maternal chromosome in the brain. X chromosome inactivation in females is different from imprinting in this regard in that it is presumed to be present in all somatic cells.

Although imprinting affects only a few chromosomal regions, imprinted genes contribute to genetic diseases. The phenotypes exhibited by moles and teratomas are the result of failure to receive either the maternal (mole) or paternal (teratoma) genome. Other phenotypes result from failure to receive specific portions of the maternal or paternal genome, or inappropriately receiving two copies of the same chromosome region from one parent and none from the other parent (uniparental disomy or UPD) (87). A fraction of cases of Prader–Willi syndrome (PWS), Angelman syndrome, and Beckwith–Wiedemann syndrome result from such imbalances in the parental origin-dependent of a chromosome region. In the case of PWS, about 70% of the patients have a deletion in the proximal q arm of the paternally inherited chromosome 15. In normal individuals, the PWS critical gene(s) are transcribed only from the paternal homolog. Therefore, with the deletion of the PWS critical region on the paternal 15, PWS patients are completely deficient for the products of these imprinted genes. The remaining 30% of PWS patients have two chromosome 15s derived from their mother and none from their father. In the absence of a paternal 15, these patients also lack the expression of PWS critical gene(s). A likely mechanism for the origin of this UPD is the conception of a fetus with trisomy for chromosome 15 with two chromosomes from the mother and one from the father. Trisomy 15 is usually lethal and will lead to miscarriage. However, loss of a chromosome 15 in an occasional cell during early embryogenesis will allow that cell line to proliferate and result in a viable fetus. If the sole paternal chromosome is the one that is lost in this trisomy rescue, the resulting infant will have maternal UPD and PWS. Alternatively, UPD could arise from the rescue of a monosomic conceptus, by duplication of the single homolog. Maternal and paternal UPDs for many of the human chromosomes have now been identified. Several of these result in a normal phenotype, presumably because the chromosome does not harbor any imprinted gene(s) (87). However, these individuals may be at risk for being homozygous for recessive genes. The possible role of UPD, a unique form of chromosomal inheritance, in disease states of unknown etiology is being investigated.

## 10.8 CHROMOSOME ABNORMALITIES

Human cytogenetics has advanced during the past four decades because of continuing technical advances and the high incidence of chromosome abnormalities in the human population. It is estimated that the frequency of

significant chromosome abnormalities among live births is about 1 in 150. It is well documented that about 50% of first-trimester pregnancy losses are due to chromosome abnormalities, mostly numerical anomalies. Thus chromosome aberrations have a significant impact as causes of pregnancy wastage, congenital malformations, mental retardation, abnormalities of sex differentiation, and behavior problems. Acquired chromosomal changes play a significant role in carcinogenesis and in tumor progression.

Most chromosomal abnormalities exert their phenotypic effects by increasing or decreasing the quantity of genetic material. Chromosomal abnormalities can be divided into numerical and structural abnormalities. Structural changes such as translocations and inversions pose a much more serious familial recurrence risk for chromosome abnormalities. This is due to aberrant segregation of chromosomes during meiosis in clinically normal carriers of these balanced rearrangements.

### 10.8.1 Numerical Chromosome Abnormalities

The most straightforward of chromosomal abnormalities are alterations of chromosome number. Deviation from the normal diploid complement of 46 chromosomes is referred to as “aneuploidy”; an extra chromosome results in “trisomy,” whereas a missing chromosome results in “monosomy.” Although all the possible chromosomal trisomies have been observed in spontaneous abortions, trisomies 13, 18, and 21 are the only autosomal trisomies to be observed in a nonmosaic state in liveborns, and are discussed in detail in Chapter 43. All autosomal monosomies are lethal. The only viable monosomy involves the X chromosome (45,X resulting in Turner syndrome). Abnormalities associated with sex chromosomes are discussed in detail in Chapter 44. Aneuploidy results from nondisjunction, in which two copies of a chromosome go to the same daughter cell during meiosis or mitosis. Nondisjunction occurs most often in the first meiotic division in the maternal germ line. In meiosis I nondisjunction, both homologs of a chromosome move to the same pole during anaphase I instead of moving to opposite poles, giving rise to one daughter cell with two copies of the chromosome and the other with none. The latter product is never recovered because of lethality associated with monosomy. In the case of meiosis II nondisjunction, the two sister chromatids of a homolog move to the same pole, again giving rise to one daughter cell with two copies of the chromosome and the other with none. Mitotic nondisjunction results in the presence of an aneuploid and a normal cell line—a condition referred to as “mosaicism.” The causes of nondisjunction are unknown. The only well-documented risk factor is advanced maternal age.

The term “polyploidy” on the other hand refers to the presence of a complete extra set of chromosomes;

“triploidy” represents three sets with 69 chromosomes, whereas “tetraploidy” represents four sets with 92 chromosomes. Rarely, a triploid fetus will be liveborn, but in general polyploidy is lethal. In few instances, however, mosaicism for a diploid and a triploid cell line producing congenital anomalies has been compatible with long-term survival.

### 10.8.2 Structural Chromosome Abnormalities

Structural chromosomal rearrangements result from chromosome breakage with subsequent reunion in a different configuration. They can be balanced or unbalanced. In balanced rearrangements, the chromosome complement is complete with no loss or gain of genetic material. Consequently, balanced rearrangements are generally harmless, with the exception of rare cases in which one of the breakpoints disrupts an important functional gene. Carriers of balanced rearrangements are often at risk of having children with an unbalanced chromosome complement. When a chromosome rearrangement is unbalanced, the chromosome complement contains an incorrect amount of genetic material, usually with serious clinical effects.

A deletion involves loss of part of a chromosome and results on monosomy for that segment of the chromosome, whereas duplication represents the doubling of part of a chromosome, resulting in trisomy for that segment. The result is either decrease or increase in gene dosage. In general, duplications appear to be less harmful than deletions. Very large deletions usually are incompatible with survival to term. Deletions or duplications larger than ~5 Mb in size can be visualized under the microscope using G-banded chromosome analysis. Genomic disorders resulting from submicroscopic deletions and duplications (i.e. microdeletions and microduplications) with a size <5 Mb have been identified with the help of molecular cytogenetic techniques. In these syndromes, groups of contiguous genes are either deleted or duplicated, resulting in a defined set of congenital anomalies.

The use of cytogenomic arrays, including array CGH and SNP arrays, to analyze the genomes of normal humans led to the discovery of extensive genomic benign copy number variations (CNVs), both gains and losses, with the majority <500 kb in size (88,89). Benign CNVs have been proposed to be a major factor responsible for human diversity (90). Through genomic rearrangement of rearrangement-prone regions as a result of the genomic architecture, pathogenic CNVs on the other hand can cause genomic disorders due to losses or gains of dosage sensitive gene(s) resulting in a clinical phenotype (91). These pathogenic CNVs include recurrent microdeletions and microduplications flanked by segmental duplication (also called low copy repeats) and mediated by nonallelic homologous recombination, as well as non-recurrent deletions and duplications, varying

in size from a few hundred kilobases to a few megabases, and mediated by other molecular mechanisms (92,93). Well-known genomic disorders can be phenotypically heterogeneous and variable due to incomplete penetrance or variable expression. Clinical variability could also be explained in part by other genetic or environmental determinants, modifying factors of other genes, multigenic inheritance, imprinting, and unmasking of recessive genes. Cytogenomic arrays are proving particularly effective for the investigation of patients with developmental delay, intellectual disability, autistic features, dysmorphic features, and/or multiple congenital anomalies, and are identifying the probable underlying cause of the disease phenotype in approximately 15–20% of previously undiagnosed cases (44,91,94).

Translocations involve the exchange of genetic material between chromosomes. In a balanced reciprocal translocation the exchange is equal, with no loss or gain of genetic material, though it is possible for a gene to be disrupted at one of the breakpoints. More often, the carrier of a balanced translocation is free of clinical signs or symptoms but is at risk for having offspring with unbalanced chromosomes. The phenotype usually is a complex mixture as a result of loss or gain of at least two chromosome segments and therefore can be difficult to predict. One specific type of translocation that is relatively common is the “Robertsonian translocation.” This results from a fusion of two acrocentric chromosomes at the centromere. Carriers of a Robertsonian translocation have 45 chromosomes and are clinically unaffected. The most common clinically significant outcome is trisomy 21, in which a carrier for a Robertsonian translocation involving chromosome 21 produces a gamete with both the translocation chromosome and a normal 21, resulting in trisomy 21 after fertilization.

Inversions occur when there are two breaks in a chromosome and the intervening material flips 180°. Inversions that span the centromere are referred to as “pericentric,” whereas those that do not are called “paracentric.” Inversions generally do not result in added or lost genetic material, and therefore usually are viewed as neutral changes. Disruption of a gene at one of the breakpoints, however, could change the function of that gene. Also, alteration of gene order at the borders of the inversion could affect the function of blocks of genes that are coordinately regulated (“position effect”). If a crossover occurs in the inverted segment of a pericentric inversion during meiosis, two recombinant chromosomes result, one with duplication of one end and deletion of the other end, and the other having the opposite arrangement. Such a crossover event in a paracentric inversion results in dicentric or acentric chromosomes that tend to be unstable.

An insertion occurs when a segment of one chromosome becomes inserted into another chromosome. Because these changes require three chromosomal breakpoints, they are relatively rare. Abnormal segregation in

a balanced insertion carrier can produce offspring with either duplication or deletion of the inserted segment, as well as balanced carriers and normal offspring.

A “marker” chromosome is a rearranged chromosome whose genetic origin is unknown based on its G-banded chromosome morphology. Usually they are present in addition to the normal chromosome complement and are thus called supernumerary marker chromosomes (SMCs). Two-thirds of de novo marker chromosomes can be associated with an abnormal outcome, whereas inherited ones can be passed from generation to generation without apparent clinical effects. Larger markers with more genetically active material are more likely to be of clinical significance. FISH and cytogenomic arrays have proved very helpful in the precise identification of the genetic origin of SMCs. Ring chromosomes are formed when a chromosome undergoes two breaks and the broken ends reunite in a ring structure. Rings encounter difficulties in mitosis and are unstable, resulting in some cells that lose the ring and are therefore monosomic for the chromosome, and others that have multiple copies of the ring. An “isochromosome” is a chromosome in which one arm is missing and the other duplicated in a mirror-image fashion. The most commonly encountered isochromosome is that which consists of two long arms of the X chromosome. This accounts for ~15% of all cases of Turner syndrome (95).

## 10.9 CONCLUDING REMARKS

In this chapter, we have outlined the structural, functional, and behavioral aspects of human chromosomes and their relationship to disease states. Although recent investigations have provided insights into several aspects of chromosome structure, the details of the higher order structure of chromosomes are not well understood at the molecular level in full detail.

We have begun to understand the DNA sequences that are associated with chromosomal landmarks, such as centromeres, telomeres, chromosome bands, and fragile sites. However, we still do not understand the role of such sequences in producing the associated functional correlates. For example, which sequences are critical for centromere function, and how do dicentric chromosomes decide which will function? Most enigmatic, what is the origin of chromosome bands and what is the molecular organization of a band border?

The availability of the finished human genome sequence and cytogenomic arrays has allowed the detection of genomic CNVs on a global scale. It is now appreciated that the underlying genomic architecture plays a crucial role in the origin of these genomic rearrangements in rearrangement-prone regions. Segmental duplications have arisen in the primate genome, driving the process of chromosome evolution. In addition to creating a dynamic, evolvable genome, these segmental duplications result in instability, genomic rearrangement, and disease. We

have begun to understand the organization of segmental duplications, which predisposes the chromosomes that carry them to germline genomic rearrangements such as deletions, duplications, and inversions. However, we do not understand the mechanisms that initially led to the formation of segmental duplications, nor the sequences or structures responsible for their continued instability.

Many new insights have come from understanding the structure and function of the human X chromosome and genomic imprinting. However, we do not know to what extent the remainder of the genome may contain imprinted or partially imprinted genes whose parental origin in part determines tissue-specific expression. Might such “epigenetic” phenomena provide another mechanism for both normal human variation and disease susceptibility?

Much remains to be learned about the molecular aspects of chromosome structure, function, and behavior. It is anticipated that the human genome sequence and its functional characterization will provide the tools with which to approach these problems and define a new frontier for the role of chromosomes in human disease.

## GLOSSARY

- Aneuploidy** – a chromosome constitution with one or more chromosomes extra or missing from a full diploid set.
- Autosome** – any chromosome other than the sex chromosomes X and Y.
- BAC (bacterial artificial chromosome)** – a recombinant plasmid in which up to ~300 kb piece of genomic DNA can be cloned and propagated in bacterial cells.
- Bivalent** – a four-strand structure seen in meiotic prophase I comprising two synapsed homologous chromosomes.
- Centromere** – the primary constriction of a chromosome separating the short (p) arm from the long (q) arm. This is the point at which spindle fibers attach to pull chromatids apart during cell division.
- Chiasma (plural: chiasmata)** – the physical manifestation of meiotic crossover as seen under the microscope.
- Chromatid** – from the end of S phase of the cell cycle until anaphase of cell division, a chromosome consists of two sister chromatids. Each contains a complete double helix and the two are exact copies of each other.
- Chromatin fiber** – the 30 nm coiled coil complex of DNA and histones that is believed to be the basic conformation of chromatin.
- Comparative genomic hybridization (CGH)** – use of competitive fluorescence in situ hybridization to detect chromosomal regions that are gained or lost.
- Constitutional** – a genotype, chromosomal abnormality, or mutation that was present in the fertilized egg and therefore present in all cells of a person. This is distinct from a somatic change.
- Contiguous microdeletion/microduplication syndrome** – a syndrome caused by either deletion or its reciprocal duplication of a group of contiguous genes, some of which are dosage sensitive and contribute to the phenotype.

**Denaturation** – dissociation of complementary strands to give single-stranded DNA.

**Diploid** – have two copies of each chromosome.

**Dosage sensitive** – property of a gene where two copies of that gene are required for its normal function. A change in copy number produces an abnormal phenotype.

**Euchromatin** – the fraction of the nuclear genome which contains transcriptionally active genes and adopts a relatively extended conformation unlike heterochromatin.

**Fluorescence in situ hybridization (FISH)** – in situ hybridization using fluorescently labeled DNA probes.

**Haploid** – describing a cell, typically a gamete, which has only one copy of each chromosome.

**Heterochromatin** – a chromosomal region that remains highly condensed throughout the cell cycle and shows little or no evidence of active gene expression.

**Homologous chromosomes** – the two copies of a chromosome in a diploid cell. Unlike sister chromatids, homologous chromosomes are not copies of each other but one paternal in origin and the other maternal in origin.

**Imprinting** – determination of the expression of a gene by its parental origin.

**Interphase** – all the time in the cell cycle when the cell is not dividing.

**Isochromosome** – an abnormal symmetrical chromosome consisting of two identical arms, which are normally either the short (p) arm or the long (q) arm of a normal chromosome.

**Karyotype** – a summary of the chromosome constitution of a cell or a person.

**Marker chromosome** – an abnormal chromosome of unidentified origin.

**Metaphase** – the stage of cell division when chromosomes are maximally contracted and line up on the equatorial plane of a cell.

**Microdeletion** – a chromosomal deletion that is too small to be seen using conventional chromosome banding techniques (typically <5Mb).

**Monosomy** – having only one copy of a particular chromosome.

**Mosaic** – an individual who has two or more genetically different cell lines derived from a single zygote.

**Nondisjunction** – failure of chromosomes to separate at anaphase and is a major cause of numerical chromosome abnormalities. It can involve sister chromatids in mitosis or meiosis II or paired homologs in meiosis I.

**Nucleolar organizer regions (NORs)** – the stalks of the short (p) arms of chromosomes 13, 14, 15, 21, and 22. NORs contain arrays of ribosomal RNA genes.

**Nucleosome** – the basic structural unit of chromatin.

**Paracentric inversion** – inversion of a chromosomal segment that does not include the centromere.

**Pericentric inversion** – inversion of a chromosomal segment that includes the centromere.

**Polyploid** – having multiple chromosome sets as a result of a genetic event.

**Pseudoautosomal region** – regions at each tip of the X and Y chromosomes and containing X–Y homologous genes.

**Segmental duplication** – a very highly homologous DNA sequence block on different chromosomes or at more than one location within a chromosome.

**Sister chromatid** – two chromatids present within a single chromosome and joined at the centromeres.

**Telomere** – a specialized structure at the tips of chromosomes.

**Translocation** – exchange of genetic material between chromosomes.

**Triploid** – having three copies of the genome.

**Trisomy** – having three copies of a particular chromosome.

**Uniparental disomy (UPD)** – having both copies of one particular chromosome pair derived from one parent.

### Biography

**Dr Mikhail** graduated from the Faculty of Medicine, University of Alexandria, Egypt in 1990. He completed his clinical pathology residency at the Department of Clinical Pathology in the same University. He received an Egyptian government scholarship to conduct this PhD thesis research work in the United States where he worked as a visiting scholar in the Pathology Department, School of Medicine, University of Illinois at Chicago, IL. He earned his PhD from the Faculty of Medicine, University of Alexandria, Egypt in 2003. Dr Mikhail did his clinical cytogenetics fellowship at the Department of Genetics, School of Medicine, University of Alabama at Birmingham, AL, and was certified by the ABMG in 2007. He joined the faculty in the Department of Genetics, School of Medicine, University of Alabama at Birmingham, AL as an assistant professor in 2006. His research interests include identification of novel constitutional genomic disorders caused by microdeletions and microduplications using cytogenomic array methodologies with special interest in neurodevelopmental disorders, and characterization of the clinical phenotype, molecular breakpoints, mechanism of rearrangement, as well as the functional categorization of the involved genes. Dr Mikhail's research interests also include identification of novel cytogenetic rearrangements in patients with various hematological malignancies that might have a causal role in the oncogenic process using molecular cytogenetic techniques, and identification of the underlying genes.

### ABBREVIATIONS

AAV – Adeno-associated virus  
 ALA –  $\delta$ -aminolevulinic acid  
 ALS – Amyotrophic lateral sclerosis  
 AML – Acute myeloid leukemia  
 AMPK – Adenosine monophosphate activate protein kinase  
 ANT – Adenine nucleotide translocator  
 ASDs – Autism spectrum disorders  
 BPAD – Bipolar affective disorder  
 CNVs – Copy number variants  
 DCA – Dichloroacetate  
 DSAD – Down syndrome and dementia  
 ER – Endoplasmic reticulum  
 ETC – Electron transport chain  
 ETF – Eelectron transfer flavoprotein  
 FH – Fumarate hydratase  
 FICP – Fatal infantile cardiomyopathy plus  
 FMN – Flavin mononucleotide  
 HSP – Hereditary spastic paraplegia  
 IBM – Inclusion body myopathy  
 IDDM – Insulin-dependent diabetes mellitus  
 LHON – Leber hereditary optic neuropathy  
 MAMs – Mitochondrial-associated membranes  
 MELAS – Mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes  
 MERRF – Myoclonic epilepsy with ragged red fibers  
 MM – Mitochondrial myopathy  
 MNGIE – Mitochondrial neurogastrointestinal encephalomyopathy

MODY – Maturity onset of diabetes in the young  
 MPTP – 1-Methyl-4-phenyl-1,2,3,4,-tetrahydropyridine  
 mRNA – Messenger RNA  
 MnSOD – Manganese superoxide dismutase  
 mtDNA – Mitochondrial DNA  
 mtPTP – Mitochondrial permeability transition pore  
 MTS – Mitochondrial targeting sequence  
 NASH – Nonalcoholic steatohepatitis  
 nDNA – Nuclear DNA  
 NMR – Nuclear magnetic resonance  
 NOS – Nitric oxide synthase  
 NRF1, NRF2 – Nuclear respiratory factors 1 and 2  
 OXPHOS – Oxidative phosphorylation  
 PBR – Peripheral benzodiazepine receptor  
 PCR – Polymerase chain reaction  
 PDH – Pyruvate dehydrogenase  
 PDK – Pyruvate dehydrogenase kinase  
 PEO – Progressive external ophthalmoplegia  
 PHDs – Prolyl hydroxylases  
 PNAs – Protein nucleic acids  
 PPAR $\gamma$  – Peroxisome-proliferation-activated receptor  $\gamma$   
 REDOX – Reduction–oxidation  
 ROS – Reactive oxygen species  
 RRFs – Ragged-red muscle fibers  
 SDH – Succinate dehydrogenase  
 SNPs – Single nucleotide polymorphisms  
 tRNA – Transfer RNA  
 UCPs – Uncoupling proteins  
 YBP – Years before present

A wide variety of degenerative and metabolic diseases as well as cancer and aging have now been associated with mitochondrial dysfunction. These can result from mutations in either the mitochondrial DNA (mtDNA) or the nuclear DNA (nDNA) or due to a dysfunctional interaction of the two genomes. Hence, the genetics of mitochondrial diseases can be non-Mendelian and complex.

The mitochondria generate much of the cellular energy by burning hydrocarbons with oxygen via oxidative phosphorylation (OXPHOS), thus generating ATP to do work and produce heat to maintain body temperature. As a result, the mitochondria regulate cellular reduction-oxidation (REDOX) status, produce much of the cellular reactive oxygen species (ROS), control cellular calcium ( $\text{Ca}^{++}$ ) levels, provide subcellular compartmentalization for numerous cellular functions, and can initiate cell death (apoptosis) when mitochondrial energetics is compromised through the activation of the mitochondrial permeability transition pore (mtPTP).

Currently recognized mitochondrial diseases can either be stereotypic in their presentation, as in Leber hereditary optic neuropathy (LHON) or the Leigh syndrome (LS), or result in variable multisystem disorders that generally affect the more oxidative organs of the body, including the central nervous system, skeletal muscle, heart, renal, and/or endocrine systems, though any organ system may be involved. Moreover, as knowledge of the complex biology and genetics of the mitochondrion continue to advance, it is becoming increasingly recognized that mitochondrial dysfunction plays a central role in a broad spectrum of metabolic and degenerative diseases as well as cancer and aging. Hence, the emerging field of Mitochondrial Medicine is impacting virtually every aspect of modern medicine (1).

The eukaryotic cell is the product of an over two billion year old symbiosis between two coequal single-celled organisms, one of which became specialized in encoding the cellular and organismal structure and ultimately gave rise to the nucleus-cytosol while the other became specialized in energy production and led to the modern mitochondrion. The exchange of genes between these two organisms ultimately generated an organism in which all of the genes for structure were all stored in the nDNA while the critical genes for the wiring diagram of mitochondrial energy production were retained in the mtDNA (2).

The energy production capacity of one bacterial cell is to sustain in the order of 2000–3000 genes. Hence, the genome size of all prokaryotic organisms is limited. However, with the advent of the nucleus-cytosol and mitochondrion symbiosis, the number of mitochondria within the cellular cytoplasm could increase. Since many mitochondria could contribute to the energy needed to sustain the nucleus, the energetic limitation of gene number was relieved, permitting the accumulation of over 10 times more genes in the eukaryotic cell nucleus than the prokaryotic nucleoid and thus providing the

information necessary for multicellularity and the elaboration of complex anatomical forms (3). Indeed, genomic energy limitation may have been a major driving force for the transfer of the mtDNA genes to the nucleus. Placing a copy of each essential mitochondrial gene in the nucleus permitted the nuclear gene to supply the protein to all of the mitochondria. The deletion of that gene from all of the mtDNAs then freed up energy previously required for mitochondrial gene replication and expression for use in fostering nuclear gene replication and expression.

Hence, life is the product of the interplay between structure (anatomy), energy (vital force), and information (the information required to encode for both structural and energetic systems) (2). “Western” medicine, however, has traditionally taken an anatomical perspective on health and disease. As a consequence, the central role of bioenergetics and its genetics has been largely overlooked in the health sciences.

The identification and description of specific mtDNA mutations that cause either stereotypic or multisystem diseases such as Leber hereditary optic atrophy (4), myoclonic epilepsy and ragged red fiber (MERRF) disease (5,6), and chronic progressive external ophthalmoplegia (CPEO) (7) have demonstrated the importance of mutations in energy genes to health. The characterization of these and numerous other mitochondrial diseases has since revealed the complex, multisystem, degenerative nature of the clinical phenotypes resulting from chronic energy deficiency. This has set the stage for the reassessment of the pathophysiology of a broad range of metabolic and degenerative diseases, cancer, and aging (1,8,9).

As our understanding of mitochondrial biology and genetics has expanded, several new biomedical paradigms have emerged which are helping the understanding of the pathophysiology of common complex diseases. The first paradigm is that the integrated system of mitochondrial biochemistry and biophysics plays a multidimensional role in human health and disease. Hence, the tradition linear concept of one gene-one polypeptide-one disease is no longer meaningful. Rather, alterations in bioenergetics must be analyzed through systems biology. The second is that “inheritance” is no longer defined exclusively by the rules of Mendelian genetics. Heredity also involves non-Mendelian (maternal) genes, nuclear-cytoplasmic interactions, somatic genetic alterations, and the energetic regulation of cellular metabolism and nDNA gene expression through the cellular signal transduction systems and the epigenome. The third is that different organs and tissues have different energetic demands and energetic functions, the energy anatomy. As a consequence, systemic defects can result in tissue and organ specific symptoms.

In this chapter, we will attempt to summarize the salient features of mitochondrial biology and genetics and then to apply these insights to interpreting the

genetics and pathophysiology of both established mitochondrial diseases and common complex disease. In this way, we hope to provide a more comprehensive understanding of genetic disease which has greater predictive power for clinical diagnosis, genetic counseling, and therapeutic development.

## 11.1 MITOCHONDRIAL BIOLOGY AND GENETICS

The mitochondrion has a characteristic double membrane structure (Figure 11-1). The outer membrane is smooth, but the inner membrane is highly folded, forming structures called cristae. The large surface area of the inner mitochondrial membrane accommodates the enzymes of the mitochondrial energy-generating apparatus, OXPHOS.

### 11.1.1 Mitochondrial Biology and the Etiology of Disease: Energy Production, ROS Generation, Apoptosis, and Mitochondrial Dynamics

OXPHOS is composed of five multi-polypeptide enzyme complexes. Complexes I, II, III, and IV make up the electron transport chain (ETC), while complex V is the ATP synthase (ATPsyn) (see Figure 11-1). Dietary carbohydrates and fats are transported to the mitochondria, where they are oxidized by the tricarboxylic acid cycle and the  $\beta$ -oxidation pathways, respectively. This liberates  $\text{CO}_2$  and hydrogen atoms, the latter being transferred to soluble NAD to generate  $\text{NADH} + \text{H}^+$ , or to FAD bound within enzymes to yield  $\text{FADH}_2$ .  $\text{NADH} + \text{H}^+$  is oxidized by complex I (NADH:ubiquinone oxidoreductase, EC 1.6.5.3) and the electrons are transported through flavin

**FIGURE 11-1** Mitochondrial processes involved in energy production, REDOX regulation,  $\text{Ca}^{++}$  homeostasis, RPS production, and regulation of apoptosis through the mtPTP. The OXPHOS complexes, designed I to V, are complex I (NADH: ubiquinone oxidoreductase) encompassing a flavin mononucleotide (FMN) and six Fe-S centers (designated with a cube); complex II (succinate: ubiquinone oxidoreductase) involving a flavin adenine dinucleotide (FAD), three Fe-S centers, and a cytochrome b; complex III (ubiquinol: cytochrome c oxidoreductase) encompassing cytochromes b, c1 and the Rieske Fe-S center; complex IV (cytochrome c oxidase) encompassing cytochromes a+a<sub>3</sub> and CuA and CuB; and complex V (H<sup>+</sup>-translocating ATP synthase). Pyruvate from glucose enters the mitochondria via pyruvate dehydrogenase (PDH), generating acetylCoA which enters the TCA cycle by combining with oxaloacetate (OAA). Cis-aconitase converts citrate to isocitrate and contains a 4Fe-4S center. Lactate dehydrogenase (LDH) converts excess pyruvate plus NADH to lactate. Small molecules diffuse through the outer membrane via the voltage-dependent anion channel (VDAC) or porin. The VDAC together with ANT, Bax, and the cyclophilin D (CD) protein are thought to come together at the mitochondrial inner and outer membrane contact points to create the mtPTP. The pro-apoptotic Bax of the mtPTP is thought to interact with the anti-apoptotic Bcl2 and the benzodiazepine receptor (BD). The opening of the mtPTP is associated with the release of several pro-apoptotic proteins. Cytochrome c (cyt c) interacts with and activates cytosolic Apaf-1, which then binds to and activates procaspase-9. The activated caspase-9 then initiates the proteolytic degradation of cellular proteins. Apoptosis initiating factor (AIF) and endonuclease G (EndoG) have nuclear targeting peptides that are transported to the nucleus and degrade the chromosomal DNA. (Modified from Reference (317).)

mononucleotide (FMN) and multiple iron-sulfur centers until they are transferred to ubiquinone, or coenzyme Q<sub>10</sub> (CoQ<sub>10</sub>). CoQ<sub>10</sub> is subsequently reduced to ubisemiquinone (CoQ<sub>10</sub>H), and then to ubiquinol (CoQ<sub>10</sub>H<sub>2</sub>). CoQ<sub>10</sub> is also reduced to CoQ<sub>10</sub>H<sub>2</sub> by succinate through complex II (succinate:ubiquinone oxidoreductase, EC 1.3.5.1) and by electrons from fatty acid oxidation via the electron transfer flavoprotein (ETF) together with the ETF dehydrogenase (EC 1.5.5.1). Both succinate dehydrogenase (SDH) and ETF dehydrogenase contain an FAD molecule and one or more iron-sulfur centers. CoQ<sub>10</sub>H<sub>2</sub> ferries the electrons through the inner membrane to complex III (ubiquinol:ferrocytochrome c oxidoreductase [EC 1.10.2.2] or the bc<sub>1</sub> complex). Within this complex, the electrons move through the Q cycle, cytochrome b, cytochrome c<sub>1</sub>, and the Rieske iron-sulfur components. The electrons are then transferred from complex III to cytochrome c, which is loosely associated with the exterior of the inner membrane. Cytochrome c transfers the electrons to complex IV (ferrocytochrome c: oxygen oxidoreductase [EC 1.9.3.3.1] or cytochrome c oxidase [COX]). Within this complex, the electrons are transferred through the Cu<sub>A</sub> and Cu<sub>B</sub> centers and cytochromes a and a<sub>3</sub> and ultimately combine with ½O<sub>2</sub> to give H<sub>2</sub>O (actually, four electrons reduce O<sub>2</sub> to 2H<sub>2</sub>O). The energy that is released in this controlled oxidation of the electrons is used to pump protons from inside the mitochondrial matrix across the inner membrane into the intermembrane space through complexes I, III, and IV. The resulting electrochemical gradient, Δp, which combines ΔpH (ΔμH<sup>+</sup>) and an electrostatic potential (Δψ) (i.e. Δp = Δψ + ΔpH), serves as a source of potential energy for synthesizing ATP. ATP is synthesized by complex V (ATP phosphohydrolase [H<sup>+</sup> transporting; EC 3.6.1.34], or ATPsyn), which contains three distinctive components: the base, F<sub>0</sub>, the stalk, and the hexagonal head, F<sub>1</sub>. As protons move back through the proton channel in F<sub>0</sub>, they cause the central axle of the ATPsyn to spin within the hexagonal array of 3α and 3β subunits, causing them to change their conformation. This causes ADP and Pi to bind, be condensed into ATP, and be released into the matrix. Matrix ATP is exchanged for cytosolic ADP by the adenine nucleotide translocator (ANT) (8–10) (see Figure 11-1).

Each of the ETC complexes incorporates multiple electron carriers. Complexes I, II, and III encompass several Fe-S centers, as does aconitase of the tricarboxylic acid cycle. Complexes III and IV encompass the cytochromes (8,9,11).

Since the ETC is coupled to ATP synthesis through Δp, mitochondrial oxygen consumption is regulated by the matrix concentration of ADP. In the absence of ADP, oxygen consumption is slow (state IV respiration). However, when ADP is added, it is transported into the matrix by the ANT, and oxygen consumption goes up as ATPsyn utilizes the proton gradient to phosphorylate ADP back to ATP (state III respiration). The ratio

of state III and state IV respiration is called the respiratory control ratio, and the amount of molecular oxygen consumed relative to the ADP phosphorylated is the P:O ratio. Addition of uncouplers such as 2,4-dinitrophenol and FCCP collapse Δp and permit the ETC and oxygen consumption to run at their maximum rates.

Because OXPHOS is a major sink for reducing equivalents in the cell, it is a major factor in regulating the cellular REDOX state. The REDOX state, in turn mediated a wide range of cellular metabolic and gene expression functions through reversible thiol-disulfide reactions occurring within numerous enzymes and transcription factors (12). Similarly, almost no function within the cell can proceed without the input of energy. As a result, all signal transduction pathways in the cell and the status of the epigenome are modulated by phosphorylation by ATP and/or acetylation by acetyl-CoA, both of which are primarily generated by the mitochondrion (13).

The mitochondrial membrane potential being negative in the matrix provides an electrostatic system for the import of a range of positively charged molecules into the mitochondrion. This includes the cytosolically synthesized polypeptides destined to be imported back into the mitochondrion as well as positively charged ions including calcium (Ca<sup>++</sup>) which is mediated by a specific mitochondrial Ca<sup>++</sup> uniporter (14,15).

The mitochondria are also the primary source of endogenous ROS. The first of the ROS, superoxide anion (O<sub>2</sub><sup>-</sup>) is generated by the transfer of one electron from the ETC to O<sub>2</sub> (see Figure 11-1). Ubisemiquinone, localized at the CoQ binding sites of complexes I, II, and III, appears to be the primary electron donor (16–19).

Mitochondrial O<sub>2</sub><sup>-</sup> is converted to H<sub>2</sub>O<sub>2</sub> by manganese superoxide dismutase (MnSOD) and the resulting H<sub>2</sub>O<sub>2</sub> is reduced to water by glutathione peroxidase-1 in brain, liver, and kidney and possibly by catalase in heart and muscle. However, H<sub>2</sub>O<sub>2</sub>, in the presence of reduced transition metals, is converted to the highly reactive hydroxyl radical (•OH). The Fe-S centers of the tricarboxylic acid cycle and the ETC are the major targets of ROS reactivity. Hence, the mitochondria are particularly sensitive to oxidative stress (11,20–23).

Superoxide production and H<sub>2</sub>O<sub>2</sub> generation are highest when the ETC is more reduced (state IV respiration) and lowest when it is more oxidized (state III respiration) (24–28). Since ubisemiquinone bound to complexes I and III is probably the primary electron donor for O<sub>2</sub><sup>-</sup> generation, ROS production will be maximized under physiologic conditions that maximize the concentration of ubisemiquinone. Hence, mitochondria with primarily oxidized ubiquinone would produce minimal ROS species. However, a predominantly though not completely reduced ETC would have the maximum ubisemiquinone and hence maximal ROS production. This then explains why blocking electron flow through the ETC with drugs such as Antimycin A, which inhibits complex III, stimulates ROS production

and why also adding uncouplers further stimulates ROS production (17,25,26,28).

The mitochondria are also the major regulators of apoptosis, which is initiated through the opening of the mtPTP (see Figure 11-1). The mtPTP is thought to be composed of the peripheral benzodiazepine receptor (PBR), now known as the mitochondrial translocator protein 18kDa (TSPO) (29–32) which may form the outer membrane channel, and an unknown structure that forms the inner membrane channel. This complex interacts with the ANTs (33), cyclophilin D, and members of the pro- and anti-apoptotic Bax and Bcl2 gene family (34–36). When the mtPTP opens,  $\Delta P$  collapses fluid and ions equilibrate between the matrix and cytosol, causing the mitochondria to swell. The mechanism by which the opening of the mtPTP is coupled with the release of the inner membrane space polypeptides is unresolved. However, recent evidence indicates that the pro-apoptotic proteins Bax and Bak aggregate in the outer mitochondrial membrane to form a mega channel that permits egress of the intermembrane space proteins (37–39). The opening of the mega channel in the outer membrane results in the release of a number of cell death-promoting factors including cytochrome *c*, apoptosis initiating factor, the latent form of caspase 9 (procaspases-9), SMAC/Diablo, endonuclease G, and the Omi/HtrA2 serine protease 24. On release, cytochrome *c* activates the cytosolic Apaf-1, which activates the procaspase-9. Caspase 9 then initiates a proteolytic cascade that destroys the proteins of the cytoplasm. Endonuclease G and apoptosis initiating factor are transported to the nucleus, where they degrade the chromatin (11,40–44). Activation of the mtPTP can be mediated by a decline in mitochondrial membrane potential  $\Delta P$ ; increased oxidative stress due to excessive ROS exposure; altered REDOX status, increased matrix  $Ca^{++}$  which binds to cyclophilin D, the action of which can be inhibited by cyclosporin A; and ANT ligands including ADP, bongkrekic acid, and atractyloside (34,41). Thus, disease states that inhibit OXPHOS and increase ROS production also increase the propensity of the cell to undergo apoptosis (34,45,46).

## 11.1.2 Mitochondrial Oxidative Phosphorylation Complexes

**11.1.2.1 Complex I (NADH Dehydrogenase, NADH).** OXPHOS complex I is composed of ~45 polypeptides, 7 (MTND1, 2, 3, 4, 4L, 5, and 6) of which are encoded by the mtDNA. These encompass 3 flavoproteins, 8–9 iron-sulfur proteins (ISPs), and over 24 hydrophobic proteins (47–61).

Complex I oxidizes NADH and reduces  $CoQ_{10}$ , and uses the energy released to pump protons across the mitochondrial inner membrane. The redox differential across complex I is from  $-320\text{ mV}$  for NADH to  $+60\text{ mV}$  for  $CoQ_{10}$ . Electrons from NADH are transferred through FMN and up to eight iron-sulfur centers: N1a (NDUFV2),

N1b (NDUFS1), N2 (NDUFS7), N3 (NDUFV1), N4 (NDUFS1), N5 (NDUFS1), N6a (NDUFS8), and N6b (NDUFS8) (55,62,63). The overall structure of complex I is slipper shaped, with the foot lying in the membrane and the ankle extending into the mitochondrial matrix (64,65).

The bovine complex I consists of a globular hydrophilic region containing the NADH binding site, FMN, and all ISPs; a  $30\text{-}\text{\AA}$  diameter stalk, and a hydrophobic membrane component. The overall molecular mass is  $890\text{ kDa}$ . The hydrophilic globular component and stalk are  $175\text{ \AA}$  and have a mass of about  $520\text{ kDa}$ . The hydrophobic component is  $200\text{ \AA}$  long and has a mass of about  $370\text{ kDa}$  (64). There are 14 core subunits required for its catalytic function, 7 hydrophobic nDNA-encoded subunits (NDUFV1, NDUFV2, NDUFS1, NDUFS2, NDUFS3, NDUFS7, and NDUFS8), and 7 hydrophobic mtDNA-encoded subunits (ND1, ND2, ND3, ND4L, ND5, and ND6) (55,66).

Complex I can be split into two major components,  $I\alpha$  and  $I\beta$ , by the detergent lauryl-dimethylamine oxide. The  $I\alpha$  component can oxidize NADH and reduce ubiquinone and contains the NADH binding site, FMN, and all of the known Fe-S centers (60,67–75). The  $I\beta$  component has no enzymatic activity, is hydrophobic, and probably represents the membrane-bound component (60,76,77).

Respiratory complex I can also be subfractionated by treatment with the chaotropic anion perchlorate into three fragments: the flavoprotein fragment, the iron-protein fragment, and the hydrophobic fragment (63). The chaotropic agents *N,N*-dimethyldodecylamine *N*-oxide and  $\beta$ -mercaptoethanol also generate the subcomplexes  $I\alpha$  and  $I\beta$  (55,60,78–81). The  $I\alpha$  subcomplex harbors both hydrophilic and hydrophobic subunits including those containing the FMN and the Fe-S clusters. The  $I\alpha$  subcomplex can be subdivided into a flavoprotein component and the  $I\gamma$  fraction. The  $I\beta$  subcomplex encompasses the hydrophobic mtDNA-encoded proteins (55,66).

The crystal structure of the bacterial (*Thermus thermophilus*) (82) and the yeast (*Yarrowia lipolytica*) complex I (83) have been determined. The *T. thermophilus* enzyme is composed of 14 polypeptides whereas the *Y. lipolytica* enzyme encompasses 35 polypeptides (55). These crystal structures have led to a model as to how the transport of two electrons through complex I can result in the transport of four protons across the mitochondrial inner membrane. The membrane component is composed of two modules  $P_P$  and  $P_D$  which contain the two proton pumping channels. These encompass the ND5 and ND1 + ND6 mtDNA subunits, respectively. They are connected by a horizontal arm that is the mtDNA ND4 subunit. It is envisioned that as electrons are transferred to the bound  $CoQ_{10}$ , they drive the lateral movement of the ND4 lateral arm which then couples proton pumping through the two proton channels. Hence, the flux of two electrons results in the transport of four protons (82–84).

Complex I is affected by a wide variety of inhibitors, the best known of which are rotenone and its derivatives. One notable example of considerable clinical and experimental significance is the activated form of 1-methyl-4-phenyl-1,2,3,4-tetrahydropyridine (MPTP), 1-methyl-4-phenylpyridinium. Exposure to MPTP in both humans and other mammals results in the selective destruction of basal ganglia neurons and induction of parkinsonism (85,86).

Assembly and maintenance of active respiratory chain complexes requires the action of additional factors. While mutations have been found in several complex I structural subunit genes encoded by mtDNA or nDNA, the molecular defects that cause more than 60% of complex I patient defects have not been found by sequencing the structural genes (87).

The majority of the defects observed in complex I have proven to be mutations in assembly proteins which do not form the final structure of the complex. The first such assembly mutation was found in a patient with severe childhood-onset progressive encephalopathy leading to death at the age of 13 years. Sequencing the nDNA complex I genes and the known assembly genes revealed that the child harbored a homozygous C182T transition in exon 2 of the *B17.2L* assembly gene, resulting in a premature stop codon at position 45 (R45X) (88). Multiple complex I disease patients have now been found to have mutations in assembly genes. By analyzing the intermediate subcomplexes that accumulate in the various mutations, an assemble pathway has emerged for complex I (55).

### 11.1.2.2 Complex II (Succinate Dehydrogenase).

Complex II oxidizes succinate to fumarate and transfers the electrons to CoQ<sub>10</sub>. The enzyme is composed of four subunits: a 70-kDa flavoprotein, a 27-kDa ISP, a 15-kDa membrane polypeptide, and a 5–7-kDa membrane polypeptide. All four complex II subunits are nuclear encoded. The 70-kDa flavoprotein contains the succinate binding site and a covalently bound FAD moiety (89,90). The 27-kDa ISP contains three iron-sulfur clusters—center 1 ([2Fe-2S]<sup>2+,1+</sup>), center 2 ([4Fe-4S]<sup>2+,1+</sup>), and center 3 ([3Fe-4S]<sup>1+,0</sup>)—that transport electrons to CoQ<sub>10</sub> (91–93). CoQ<sub>10</sub> is bound to the two membrane-intrinsic subunits, CII-3 (94) and CII-4. A *b*<sub>560</sub>-type heme is also associated with CII-3 (SDHD) and CII-4 (SDHC) (95), but its function is unclear (94,96–99). However, in *Caenorhabditis elegans*, the *mev-1* mutant alters the amino acid sequence of the CII-3 (SDHD) subunit, which greatly increases ROS production and decreases life span, suggesting that cytochrome *b*<sub>560</sub> may function to stabilize or dismutate ubisemiquinone (CoQ<sub>10</sub>H) (100).

**11.1.2.3 Complex III (bc<sub>1</sub> Complex).** Complex III is composed of 11 polypeptides, one (cytochrome *b*, MTCYB) encoded by the mtDNA (101–103). The crystal structure of complex III has been determined and revealed that complex III functions as a dimer, with a monomer mass of 240 kDa (104–108). This enzyme

oxidizes ubiquinol (CoQ<sub>10</sub>H<sub>2</sub>), reduces ferricytochrome *c* to ferrocycytochrome *c*, and uses the energy released to pump protons across the mitochondrial inner membrane via the Q cycle. The polypeptides of complex III include two core proteins (subunit I and subunit II), MTCYB (subunit III), cytochrome *c*<sub>1</sub> (subunit IV), the “Rieske” ISP (subunit V), and seven smaller polypeptides, subunits 6–11. Cytochrome *b*, cytochrome *c*<sub>1</sub>, and the Rieske ISP provide the major redox centers of the enzyme (104).

The Rieske ISP and cytochrome *c*<sub>1</sub> are on the intermembrane side of the enzyme, and both contain one membrane-spanning domain. The heme cytochrome *c*<sub>1</sub> is covalently bound to Cys<sup>37</sup> and Cys<sup>40</sup> and its ligands are His<sup>41</sup> and Met<sup>160</sup> (101,109,110). Subunit 8, or the “acidic/hinge protein,” lies above cytochrome *c*<sub>1</sub>, and the two form the docking site for cytochrome *c*. The Rieske ISP encompasses a single 2Fe-2S iron-sulfur center and changes conformation, switching from intermediate (“int”), to “b,” to “c1” forms. In this process, its relationship to the adjacent cytochromes *c*<sub>1</sub> changes, facilitating directional electron flow. In the “c1” state, the iron-sulfur center is adjacent to the heme of cytochrome *c*<sub>1</sub>, in the “int” state the iron-sulfur center is displaced from both cytochromes *c*<sub>1</sub> and *b*, and in the “b” state it interacts with cytochrome *b*.

The central core of the transmembrane domain is composed of cytochrome *b*. Cytochrome *b* has a high-potential heme, *b*<sub>L</sub> (*b*<sub>566</sub>), and a low-potential heme, *b*<sub>H</sub> (*b*<sub>560</sub>). Heme *b*<sub>L</sub> is close to the intermembrane side while heme *b*<sub>H</sub> is on the matrix side. The matrix side of the enzyme is composed of the core 1 and core 2 proteins, together with subunits 6 and 9. Subunit 9 is generated by metalloprotease cleavage of the NH<sub>2</sub>-terminal 78 amino acids of the nascent Rieske ISP. Core 1 shows sequence homology to the β subunit of mitochondrial processing protease; core 2 shows homology to the α subunit. Both core proteins probably catalyze the cleavage (104).

Proton translocation of complex III is linked to electron transport through the intermediates of CoQ<sub>10</sub> oxidation–reduction in the proton-motive Q cycle (71,109,111,112). Complex III has two CoQ<sub>10</sub> binding sites, one on the cytoplasmic side (Q<sub>o</sub> or Q<sub>p</sub> site) and one on the matrix side (Q<sub>i</sub> or Q<sub>n</sub> site) of the inner membrane. Q<sub>p</sub> is on the intermembrane side close to heme *b*<sub>L</sub> and binds the inhibitor myxothiazol, while Q<sub>n</sub> is close to heme *b*<sub>H</sub> on the matrix side and binds the inhibitor Antimycin A (104,109,113–115).

CoQ<sub>10</sub>H<sub>2</sub> binds to the Q<sub>o</sub> site and transfers one electron to the Rieske ISP, which passes it on to cytochrome *c*<sub>1</sub>. The resulting ubisemiquinone donates the other electron to the adjacent *b*<sub>L</sub> heme located on the cytoplasmic side of the membrane. The transfer of the two electrons from CoQ<sub>10</sub>H<sub>2</sub> releases the two ubiquinol protons to the outside of the mitochondrial membrane. The electron at the *b*<sub>L</sub> heme is then transported to the more matrix *b*<sub>H</sub> heme, where it is transferred to CoQ<sub>10</sub> at Q<sub>i</sub> site to generate ubisemiquinone. A second molecule of CoQ<sub>10</sub>H<sub>2</sub> is

oxidized in the same manner, and the resulting  $b_H$  electron is donated to the ubisemiquinone at the  $Q_i$  site. This reduced quinone then combines with two protons from the matrix to generate ubiquinol ( $CoQ_{10}H_2$ ). Hence, two protons are transported through the membrane for each pair of electrons that exits complex III (116).

The Q cycle is driven by the conformational changes of the Rieske ISP. When complex III is oxidized, the Rieske ISP is in the “int” state. When  $CoQ_{10}H_2$  binds to the  $Q_o$  site in cytochrome *b*, the  $CoQ_{10}H_2$  is deprotonated to  $CoQ_{10}H$ , which overcomes the activation barrier. This pulls the ISP to the “b” position. An electron is transferred to the Rieske ISP while it is adjacent to the  $CoQ_{10}H$  (ubisemiquinone) in the “b” conformation. The second electron from  $CoQ_{10}H$  is then transferred to heme  $b_L$ , weakening the interaction between the quinone and the Rieske ISP, permitting the ISP to move to the “c1” state. Here it transfers the electron to cytochrome  $c_1$ , and the ISP moves to the “int” state. The cytochrome  $c_1$  electron moves on to cytochrome *c* and the heme  $b_L$  electron moves on to the heme  $b_H$  site (104).

A gene (*BCS1L*) has been shown to be responsible for a complex III assembly defect in at least four unrelated families. Mutations in this gene give a homogeneous clinical presentation associated with neonatal tubulopathy, liver failure, and encephalopathy (117). A neonatal metabolic disorder with growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death (Gracile syndrome) was also described in Finnish patients due to mutations in the *BCS1L* gene (118).

**11.1.2.4 Cytochrome c.** Cytochrome *c* ferries electrons along the outer mitochondrial membrane from complex III to complex IV. It contains a single covalently bound heme and is encoded by two isoform genes, a systemic cytochrome *c*, and a testes cytochrome *c* [(119–121), Cuticchia, 1995 #823].

**11.1.2.5 Complex IV (Cytochrome c Oxidase).** Complex IV is composed of 13 polypeptides, 3 (COI, COII, and COIII) encoded by the mtDNA. The remaining nuclear polypeptides have been designated IV, Va, Vb, VIa, VIb, VIc, VIIa, VIIb, VIIc, and VIII (122). The crystal structure of complex IV (107,123) has revealed that it is a functional dimer with a minimal monomer molecular mass of 204 kDa. Complex IV collects electrons from reduced cytochrome *c* (ferrocytochrome *c*), transfers them to CuA, then to cytochrome *a*, then to the bimetallic cytochrome  $a_3$ /CuB active site, and then to oxygen to give water, concurrently pumping four protons across the mitochondrial inner membrane (47,116,123–127).

Complex IV encompasses two hemes *a* ( $a + a_3$ ); three coppers, two for CuA and one for CuB; one magnesium; and one zinc. The two coppers forming the binuclear center, CuA, are associated with mtDNA subunit II (COII), while the two hemes and CuB (heme *a* and heme  $a_3$ -CuB) form a trinuclear center associated with mtDNA subunit I (COI). Electron flow is from cytochrome *c* to CuA, then to heme *a*, and then to the heme  $a_3$ -CuB binuclear

center, where oxygen is reduced to water (123,127,128). Molecular oxygen ( $O_2$ ) binds to the  $a_3$ -CuB binuclear center, and electron transfer to  $O_2$  is probably linked to proton transport. Complex IV uses four electrons to reduce  $O_2$  and four protons from the matrix to generate  $2H_2O$ . Four additional protons are transferred from the matrix, across the mitochondrial membrane, possibly in the proximity of heme  $a_3$  (129).

The three mtDNA-encoded subunits form the core of the monomer, with the nuclear-encoded subunits surrounding it. COI has 12 membrane-spanning domains (I–XII) that associate in three sets of four transmembrane helices forming three comma-shaped spokes radiating out from the center. COII has two transmembrane domains that lie on one side of COI, while COIII has seven transmembrane domains that lie on the opposite site of COI from COII. Finally, 7 of the 10 nDNA subunits (IV, VIa, VIc, VIIa, VIIb, VIIc, and VIII) have one membrane-spanning domain, which surrounds the core COI, COII, and COIII subunits in the membrane. The remaining three nDNA subunits (Va, Vb, and VIb) do not have transmembrane domains. Subunits Va and Vb lie on the matrix side and subunit VIb on the cytosolic side of complex IV.

Subunits II, VIa, and VIb appear to form the 25-Å diameter cytochrome *c* binding site, composed of acidic residues that interact with the basic residues of cytochrome *c* (123). The CuA coppers form a Cu–Cu bond and lie near the outside of the membrane, at the interface of COII and COI. The heme *a* and heme  $a_3$ -CuB centers are located 13 Å into the membrane. Heme *a* and heme  $a_3$  are close together, perpendicular to the membrane, and at a 104° angle relative to each other. Heme  $a_3$  is 4.5 Å from the magnesium atom and is located close to the trinuclear center, at the interface between COII and COI and ligated to both, directly between CuA and heme  $a_3$ . The zinc atom is associated with the nuclear-encoded subunit Vb on the matrix side of the enzyme, bound to cysteine residues (116,125,127,128).

Complex IV has two hydrophobic proton-conducting channels, D (Asp<sup>91</sup>) and K (Lys<sup>319</sup>), named after conserved amino acids that form the matrix sides of the channels. Channel D ends at the conserved Glu<sup>242</sup> in the middle of the membrane, which resides in a hydrophobic cavity extending toward the binuclear heme–copper center and is required for proton translocation. The K channel also ends at the binuclear center. Protons for both water formation and proton pumping move through these channels.

Proton pumping involves reduction of both metals ( $a_3$ -CuB) at the active site, with two electrons and two protons taken up. Oxygen then reacts, initially forming an oxygen intermediate. An additional electron is acquired, creating the peroxy state. Then three protons are acquired, generating the ferryl intermediate and creating an  $H_2O$  molecule and translocating two protons. A fourth electron is then accepted, resulting in a second water molecule and transport

of two additional protons. The overall reaction involves oxidation of four electrons, generation of two molecules of  $\text{H}_2\text{O}$ , and translocation of four protons (107,130).

While COIII is a universal component of all cytochrome c oxidase enzymes, its function is unclear. It does bind dicyclohexycarbodiimide (131).

The functions of the 10 nuclear-encoded subunits are still unclear. Two of the human subunits (VIa and VIIa) have two isoenzymes, one systemic and the other heart and muscle specific (125,132), that can be regulated at both the transcriptional and post-transcriptional levels (133). cDNAs have been cloned for all of the human COX genes (134–143) and the genes assigned to chromosomes (134,138,144–150).

A number of adenine nucleotide binding sites have been identified in complex IV, at least some of which can alter the kinetics of the enzyme. Five nucleotide binding sites have been found on complex IV: one between subunits I and III on the cytosolic side of the enzyme, two in subunit IV, one each on the cytosolic and matrix ends of the molecule; and two in subunit IVa, again cytosolic and matrix. In addition, three lower affinity binding sites have been detected for ADP (123,151,152). Nucleotide binding to the matrix side of subunit VIa changes the  $\text{H}^+/\text{e}^-$  stoichiometry, while nucleotide binding to the cytosolic domain of subunit IV affects the affinity of cytochrome c (151,153–156).

Complex IV is sensitive to a variety of common toxic chemicals. These include cyanide and azide, which form a bridge between cytochrome  $a_3$  and CuB, and thiocyanate and formate, which bind other locations in the binuclear center (157).

The complex structure of the respiratory complexes suggests that the assembly of active complexes requires the action of additional gene products. This has been shown to be the case for complex IV, where an additional protein, SURF-1, is required for generating normal human complex IV (COX) activity. Mutations in the *SURF1* gene have been found to be the primary cause of COX-deficient LS (158,159). *SURF1* is 25.6% homologous to the yeast gene *SHY1*. While the human *SURF1* mutation gives a specific COX defect, the yeast *SHY1* mutation is more pleiotropic. Hence, it has been suggested that SURF-1 may function in the assembly or maintenance of an active holoenzyme COX complex (158,159).

Mutations in the genes for two additional proteins involved in heme A biosynthesis, *COX10* and *COX15*, have also been found to cause complex IV deficiency. *COX10* mutations can cause LS or neonatal tubulopathy and encephalopathy (160,161), while *COX15* mutations cause fatal infantile hypertrophic cardiomyopathy or LS (162,163). Mutations in the *SCO1* and *SCO2* genes also result in complex IV deficiency. Both of these proteins are involved in inserting the copper atoms into the copper centers of complex IV (164–166).

**11.1.2.6 Complex V ( $\text{H}^+$ -Translocating ATP Synthase).** Complex V encompasses 16 polypeptides, 2 of which (ATPase6 and ATPase8) are encoded by the

mtDNA (60). This  $\text{H}^+$ -translocating ATPsyn utilizes the electrochemical gradient  $\Delta p = \Delta\psi + \Delta \text{pH}$  generated by complexes I, III, and IV to catalyze the condensation of ATP and  $\text{P}_i$  to make ATP. This enzyme uses a rotary catalytic mechanism that is close to 100% efficient.

The  $\text{F}_0$  component of the enzyme is based on the mitochondrial inner membrane, with the enzyme extending into the matrix in a lollipop shape involving a 45-Å long stalk and a 90- to 100-Å diameter barrel ( $\text{F}_1$ ). The  $\text{F}_1$  component, as isolated, is composed of five subunits— $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ , and  $\epsilon$ —with amino acid lengths of 510, 482, 272, 146, and 50 amino acids, respectively. The ratio of these subunits in the  $\text{F}_1$  particle is 3:3:1:1:1, with a total mass of about 370 kDa (71). Both the  $\alpha$  and  $\beta$  subunits are highly homologous (20% identical) and form a hexagonal array of alternating  $\alpha$  and  $\beta$  subunits. While both  $\alpha$  and  $\beta$  subunits bind nucleotides, only the  $\beta$  subunits are catalytic. The crystal structure for the  $\text{F}_1$  component shows that the  $\alpha$  and  $\gamma$  subunits form a hollow barrel into which the  $\gamma$  subunit projects up from the stalk to form an axle (167).

Based on the concept of rotary catalysis, complex V has been divided into two functional components: a “rotor” and a “stator” (168–170). The rotor consists of a hydrophobic wheel of 8 “c” (ATP9) subunits lying in the plane of the inner membrane that rotates with its axle extending into the matrix. The axle is composed of the  $\epsilon$  subunit at the base and the  $\gamma$  subunit projecting up into the  $\text{F}_1$  barrel. The stator is composed of a base made by the “a” subunit (ATP6) embedded in the membrane, adjacent to the c subunit wheel. The a (ATP6) subunit anchors a pair of “b” subunits that project out of the membrane and bind to the  $\delta$  subunit of  $\text{F}_1$ , which is attached to an  $\alpha$  subunit of the  $\alpha$ - $\beta$  barrel. Thus, the  $\text{F}_0$  subunit a (ATP6) is linked to the  $3\alpha:3\beta$  barrel in a static structure through the b subunits and  $\delta$ .

The stator subunit a (ATP6) and rotor subunit c (ATP9) interface mediates the proton flux from the intermembrane space to the matrix, thus driving the rotor’s rotation and causing the  $\gamma$  axle to spin within the  $\alpha$  and  $\beta$  subunit barrel. As the c subunit rotor spins past the “a” subunit stator, the rotor’s axle, ending in the  $\gamma$  subunit, rotates inside the hollow  $\alpha$  and  $\beta$  barrel. As it spins, the  $\gamma$  subunit makes two contacts with the  $\beta$  subunit, thus mediating the two components of the catalytic cycle. This generates sequential conformational changes in the  $\beta$  subunit nucleotide binding sites, which bind  $\text{ADP} + \text{P}_i$ , condense it to ATP, and release the ATP into the matrix (168,170).

The mechanism by which the proton motive force drives rotation of the subunit c (ATP9) rotor past the subunit a (ATP6) of the stator is highly conserved. However, the number of c subunit spokes in the wheel differs depending on the kingdom of the organism. All ATP synthases have a key negative charge in the c subunit in the middle of the membrane. This is Asp<sup>61</sup> of the c subunit of the bacterial enzyme and Glu<sup>58</sup> of the ATP6 subunit of the mammalian enzyme. This carboxylate group faces outward

from the wheel adjacent to the opposing face of the stator subunit “a” (ATP6) and also the hydrophobic core of the membrane’s lipid bilayer. The stator subunit a (ATP6) has an opposing positive charge, Arg<sup>210</sup> for the bacterial subunit c and Arg<sup>159</sup> for the mammalian subunit ATP6. This positive charge is offset 0.52 nm from the plane of carboxyl groups, such that it exerts electrostatic attraction against the Asp<sup>61</sup> of c or the Glu<sup>58</sup> of ATP9 without being capable of forming a salt bridge to stop rotation. The stator subunit c has two half-proton channels that penetrate half way into the membrane from opposite sides, but are offset from each other. One half-channel is open to the proton-rich intermembrane space, the other to the proton-poor (alkaline) matrix. In the presence of an electrochemical gradient, the half-channel open to the inner membrane space conducts in a proton to protonate the carboxyl group of subunit c (Asp<sup>61</sup>) or subunit ATP9 (Glu<sup>58</sup>), neutralizing its charge and permitting the subunit to rotate into the hydrophobic lipid bilayer without energetic inhibition. The protonated subunit c rotates all of the way around the wheel until it returns to the subunit a (ATP6) stator, where it encounters the other half-channel opening to the negatively charged and alkaline matrix. In this environment, the proton leaves subunit c (Asp<sup>61</sup>) or ATP9 (Glu<sup>58</sup>) and enters the matrix. The exposed negative charge of the Asp<sup>61</sup> of subunit c or the Glu<sup>58</sup> of ATP9 is then attracted to the displaced positive charge of the Arg<sup>210</sup> of subunit a or the Arg<sup>159</sup> of ATP6, causing the Asp<sup>61</sup> or Glu<sup>58</sup> carboxyl group of subunit c or ATP9 to rotate until it reenters the environment of the half-channel of the proton-rich intermembrane space, where it is again reprotonated (168,170–172). The stoichiometry of proton translocation to ATP synthesis differs between kingdoms because of differences in the number c polypeptides in the F<sub>0</sub> wheel. Animal mtDNAs have eight spokes in the wheel while other organisms can have up to 15 c peptides per wheel. Thus, for animals it takes eight protons to generate an ATP or 2.7 protons per ATP. For other organisms the gear ratio can be as low as 5 protons per ATP (107,173).

In the F<sub>1</sub> barrel, the three  $\alpha$  and three  $\beta$  subunits are capped by  $\beta$ -pleated sheets. Just below this cap is a hydrophobic ring forming a bearing in which the C-terminal end of the  $\gamma$  subunit rotates (167). Below the  $\beta$ -pleated sheet, and in the middle of the  $\alpha$  and  $\beta$  subunits, are the nucleotide binding sites. The conformational change and nucleotide binding sites of the  $\beta$  subunits are dynamic. The three  $\beta$  subunits sequentially go through three states: “O” or open, with very low affinity for ligands and catalytically inactive; “L” or loose, with the capacity to binding the ligands ADP and P<sub>i</sub>, but catalytically inactive; and “T” or tight, with the ligands tightly bound associated with catalysis. These three states are generated as the asymmetrical  $\gamma$  subunit interacts with the interior side of the  $\beta$  subunits (174).

The binding affinity of the  $\beta$  subunit for adenine nucleotides is modified by sequential changes in the  $\beta$  subunit conformation mediated by two “catches” that interact

with the rotating  $\gamma$  subunit. The “major catch” is a loop that protrudes into the interior of the 3 $\alpha$ :3 $\beta$  barrel. This is encountered as the  $\gamma$  subunit rotates from  $\beta$  TP (triphosphate, or tight) to  $\beta$ E (empty, or open). The  $\beta$ E conformation differs from the  $\beta$ TP and  $\beta$ DP (diphosphate, or loose) conformations in that part of the nucleotide binding site is rotated 30°. The “minor catch” separates  $\beta$ DP from  $\beta$ TP (167,175,176). These molecular interactions create a catalytic engine driven by elastic forces rather than thermal effects, which permits the near-100% efficiency (107,170).

A number of the nuclear-encoded complex V subunit cDNAs and genomic clones have been reported. The cDNAs include the ATP synthase  $\alpha$  subunit (ATPsyn $\alpha$ ) (177–179), ATPsyn $\beta$  (180,181), ATPsyn $\delta$  (182), F<sub>0</sub> subunit b (183), F<sub>0</sub> subunit F6 (184), and F<sub>0</sub> subunit 9 or c, which have three isoforms (185–189). The genomic clones include ATPsyn $\alpha$  (190,191), ATPsyn $\beta$  (192–194), and ATPsyn $\gamma$  (191,195,196), which generate two alternative messenger RNAs (mRNAs), heart-muscle and systemic (196). This is accomplished through the loss of exon 9 associated with the synthesis of a *trans*-acting factor that is inducible by high extracellular pH through a protein kinase C signaling mechanism (197).

The assembly of complex V requires the assembly protein ATP12. Mutations in the ATP12 gene have been associated with dysmorphic features, severe developmental delay, and seizures (198).

### 11.1.3 Adenine Nucleotide Translocator and Uncoupling Protein

The mitochondrial anion carrier protein family functions to transport solutes through the mitochondrial inner membrane. This group of related proteins has a tripartite repeating domain, with each domain composed of about 100 amino acids, all of which function as homodimers. This family includes two classes of carriers of particular relevance to bioenergetics, the ADP/ATP carriers or ANTs, and the uncoupling proteins (UCPs).

The ANT proteins are encoded by a small family of nDNA genes. They are multifunctional proteins that are responsible for the export of the ATP synthesized in the mitochondrial matrix by OXPHOS to the cytosol in exchange for ADP. The ANTs constitute up to 10% of the mitochondrial protein. It is thought that, as ATP binds to one of the subunits on the inside of the membrane, ADP binds to the other subunit on the outside, and the two adenine nucleotides are transported to the opposite side of the membrane, driven by the inner membrane electrochemical gradient. Each ANT monomer has six transmembrane helices and contains the consensus sequence RRRMMM, with the three Rs lying at the base of a conical well in which the adenine nucleotides bind (199).

Humans have four distinct ANT isoforms: a heart-muscle specific isoform, ANT1 (200–202); an inducible isoform, ANT2 (201,203); a systemic isoform, ANT3 (200,201); and a testis isoform, which is also expressed

at low levels in liver and brain (204). *ANT1*, which is expressed predominantly in heart and muscle (205), has four exons and a promoter with classical TATA and CCAAT elements (192,206–209). The *ANT1* gene maps to 4q35-qter, close to the FSHMD locus (210–212). *ANT2* is expressed at low levels in mature tissues, but is inducible in situations of metabolic stress and in association with increased cell proliferation (200,205,213–218). *ANT2*, which has been mapped to Xq24-q24, has the same four-exon structure as *ANT1*, a promoter with a canonical TATA and five potential Sp1 sites, but no CCAAT box (219–221). The growth regulation of *ANT2* is controlled by three of the Sp1 transcription factor binding sites: two adjacent CpG sites located together at –79 and –68 that act synergistically to induce expression following demethylation, and a third CpG site located between the TATA box and the transcriptional start site that functions as a negative regulator (222,223). *ANT2* also contains a glycolysis regulated box (GRBOX) at –1.2 kbp, a negative regulator in normal cells that is turned off in glycolytic and transformed cells (200). *ANT3* is expressed in most mature tissues as well as skin fibroblasts (205,218). It maps to Xp22.3 within the pseudoautosomal region, is expressed from both the X and the Y chromosomes, and has the classical four-exon structure. Its promoter lacks TATA and CCAAT elements, though it has potential Sp1 sites (207,224,225). In T cells, *ANT3* is regulated by either interleukin-4 or interferon- $\gamma$  through STAT6 and STAT1 (226). *ANT4* shares only 66–68% amino acid identity with the other three ANTs; yet it still retains the characteristic RRRMMM motif and exchanges ADP and ATP, though at a different kinetics. *ANT4* is located on chromosome 4q28.1 and contains six exons, instead of the usual four, and is expressed primarily in testis, though it is also significantly expressed in liver and brain (204).

In contrast to humans, the mouse has three *Ant* genes (*Ant1*, *Ant2*, and *Ant4*). The mouse *Ant1* gene maps to chromosome 8 (227,228), syntenic with human chromosome 4q35 and the human *Ant1* gene, and has the standard four exons and three introns (227). Mouse *Ant2* has been mapped to the mouse X chromosome outside the pseudoautosomal region, suggesting it is syntenic to human *ANT2* (229). No mouse homolog to the human *ANT3* gene has been isolated (227,229). The mouse homolog to human *ANT4*, designated *Ant4*, is 70.1% homologous to mouse *Ant1* and 69.1% homologous to mouse *Ant2* but 85.9% homologous to human *ANT4*. Moreover, both the mouse and the human *Ant4/ANT4* genes have the distinctive six-exon genomic structure. In adult mice, *Ant4* is expressed exclusively in testis, its mRNA being undetectable in adult heart, brain, spleen, lung, liver, skeletal muscle, or kidney by Northern blot. The *Ant4* promoter contains 47 CpGs that are extensively methylated in brain, kidney, and lung (230).

The ANTs/Ants differ in their ability to regulate the mtPTP and thus to induce apoptosis. Transformation

of cells with either the human *ANT1* or *ANT3* cDNA/gene, resulting in overexpression, strongly induces cells to undergo apoptosis. By contrast, transformation with the *ANT2* cDNA/gene does not induce apoptosis (231,232). Mitochondrial fractionation has also revealed that Ant1 is localized to the portion of the mitochondrial inner membrane in direct contact with the outer membrane and in association with hexokinase and thus the complete mtPTP. Ant2 is also distributed in the infolded cristae and is associated with mitochondrial creatine phosphokinase but not hexokinase. Hence, Ant2 is less associated with the mtPTP (233). The importance of the ANTs in regulating apoptosis has been dramatically demonstrated by their being targeted by viral peptides, presumably to regulate apoptosis (234,235). *ANT1* also binds the I $\kappa$ B $\alpha$ –NF- $\kappa$ B complex, which regulates the anti-apoptotic proteins Bcl-x<sub>L</sub>, MnSOD, and c-IAP2. *ANT2* does not interact with I $\kappa$ B $\alpha$ –NF- $\kappa$ B (236). Consequently, the upregulation of *ANT1* would reduce the available I $\kappa$ B $\alpha$ –NF- $\kappa$ B and drive the cell toward apoptosis.

The UCPs form a proton channel through the inner membrane, thus depolarizing the electrochemical gradient and uncoupling electron transport from ATP synthesis. Uncoupling protein-1 (UCP1) is primarily associated with brown adipose tissue, where it functions in thermal regulation. It is strongly induced by cold stress through a  $\beta$ -adrenergic response pathway (237–240). Uncoupling protein-2 (UCP2) has 59% amino acid identity to UCP1 and is widely expressed in adult human tissues, with mRNA levels being highest in skeletal muscle. It is also upregulated in white fat in response to an increased-fat diet. In the mouse, it has been linked to a quantitative trait locus for hyperinsulinemia and obesity (238). Uncoupling protein-3 (UCP3) is 57% identical to UCP1 and 73% identical to UCP2. UCP3 is also widely expressed in adult tissues, and at particularly high levels in skeletal muscle. Moreover, it is hormonally regulated, being induced in skeletal muscle by thyroid hormone and in white fat by  $\beta_3$ -adrenergic agonists, and also regulated by dexamethasone, leptin, and starvation. UCP3 is located adjacent to UCP2 in human chromosome 11q13 and mouse chromosome 7 (241–244).

### 11.1.4 Mitochondrial Protein Import

The mitochondrion is assembled from 13 mtDNA-encoded polypeptides and ~1000–2000 nuclear-encoded polypeptides. These polypeptides are synthesized on cytosolic 80S ribosomes and vectorially transported into the mitochondrion via receptor binding to the outer membrane and transfer through a mitochondrial inner membrane import pore. Once inside the mitochondrial matrix, the proteins are folded and assembled by the chaperone proteins mitochondrial heat shock protein 70 (mtHsp70) and mtHsp60 (245–249) (Figure 11-2).

The mitochondrial protein import apparatus encompasses a set of outer and inner membrane complexes. The Tom complexes function to transport proteins across the

**FIGURE 11-2** Proteins thought to be involved in the import of cytosolically synthesized polypeptides through the outer and inner mitochondrial membranes. The outer membrane Tom (transport across the outer membrane) complexes consist of two main receptor complexes and the general insertion pore (GIP) complex. Receptor complex Tom20 + Tom22 binds proteins with amino-terminal targeting peptides and feeds them through the GIP, of which Tom22 is thought to be a component. Tom37 + Tom70 are thought to bind proteins with internal targeting sequences and to transfer them to Tom20 + Tom22. The central channel protein of the GIP is thought to be Tom40; with Tom5, Tom6, and Tom7 also being important components. Proteins with amino-terminal targeting peptides destined for the matrix are transferred from the intermembrane space domain of Tom22 to the Tim complex. Tim23 is the central channel protein, and Tim44 binds to the preprotein as it emerges from the Tim23 channel on the matrix side. Anion carrier proteins destined for integration into the mitochondrial inner membrane, such as the ANT, follow a different pathway. As they emerge into the intermembrane space they interact with either of two soluble complexes (Tim8 + Tim9 + Tim13) or (3 Tim9 + 3 Tim10). These soluble complexes transport the protein through the intermembrane space to the other Tim complex, which is composed of Tim9 + Tim10 + Tim12 + Tim22 + Tim54. (Reprinted from (258), which was adapted from (255,1440).)

outer membrane, while the Tim complexes function to transport proteins across the inner membrane (250–252) (see Figure 11-2).

Proteins to be imported into the mitochondrion have embedded into their structure-specific mitochondrial targeting sequences. Most proteins to be imported into the mitochondrial matrix have an amino-terminal targeting peptide that is amphiphilic and basic (usually due to an excess of arginine residues). These amino-terminal targeting peptides are cleaved from the protein on import. Other proteins can have internal targeting sequences.

While in the cytosol, proteins destined for mitochondrial import interact with cytosolic chaperones. These include members of the cytosolic 70-kDa Hsp70 family, which bind to non-native proteins. In addition, there is at least one cytosolic chaperone specific for mitochondrial proteins. This is the heterochimeric mitochondrial import stimulating factor, which specifically binds matrix targeting signals. Both Hsp70 and mitochondrial import stimulating factor are ATPases (250–252).

The mitochondrial proteins, presumably maintained in a random conformation by the chaperone proteins, then interact with the receptor complexes on the mitochondrial outer membrane. Two receptor complexes have been identified: Tom20 + Tom22 and Tom37 + Tom70. Current thinking is that the Tom20 + Tom22 complex binds to proteins with amino-terminal targeting peptides. The Tom37 + Tom70 complex is thought to interact with proteins with internal targeting sequences, such as the inner membrane carrier proteins ANT and UCP. The Tom37 + Tom70 complex

then interacts with the Tom20 + Tom22 complex through a 34-amino acid “tetratricopeptide” motifs, and the Tom 20 + Tom 22 complex transfers the protein to the general insertion pore (GIP) (250–252).

The outer membrane GIP is probably composed of Tom40, Tom22, Tom5, Tom6, and Tom7 (253). Tom40 is deeply embedded in the outer membrane and forms a 22-Å hydrophilic transmembrane channel (254). Tom22 functions both as a key component of the receptor complex and an integral part of the GIP channel (250–253).

Once a protein traverses the outer membrane, it can either proceed through the inner membrane to the matrix or be inserted directly into the inner membrane. Proteins destined for the matrix with an amino-terminal targeting sequence are electrostatically attracted to the inner membrane import complex, consisting of Tim23, Tim11, Tim14, and Tim 17, and possibly Tim33. The Tim23 protein is central to this channel and, in the presence of  $\Delta\psi$ , it dimerizes, possibly providing a gating mechanism for the channel. On the matrix side, the Tim23, Tim11, Tim14, and Tim17 complex interacts with an inner membrane complex consisting of Tim44, mtHsp70, and the nucleotide exchange factor (MGE). Tim44 interacts with the preprotein as it emerges from the Tim23 pore and also binds mtHsp70. mtHsp70 then interacts with the preprotein and promotes its import, in conjunction with the hydrolysis of ATP. The interaction of Tim44 and mtHsp70 is regulated by adenine nucleotides and also by MGE, which regulates Tim44-mtHsp70 dissociation (245–252).

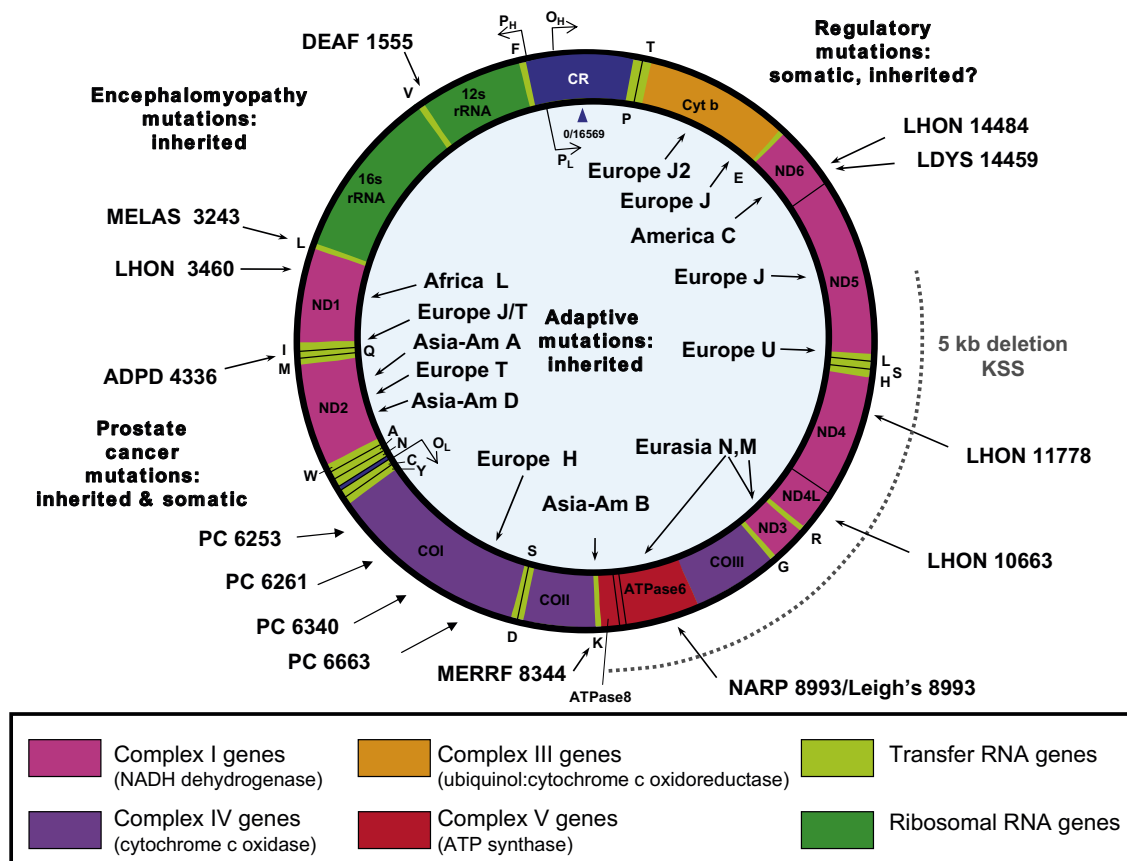

Once in the matrix, the targeting peptides are cleaved off by the mitochondrial processing peptidase, consisting of two subunits: the  $\alpha$  subunit and the catalytic  $\beta$  subunit. A subset of preproteins has a second cleavage by the mitochondrial intermediate peptidase. In the matrix, proteins are infolded by chaperone complexes (mtHsp70, MD5 and MGE, and Hsp60 and Hsp10). Mitochondrial cyclophilins, which are sensitive to cyclosporin A, can also act as folding catalysts (250–252).

Mitochondrial inner membrane transport proteins such as the ANTs and UCPs follow a different pathway. Once they enter the intermembrane space via the Tom complex, they interact with one of the two soluble complexes. One complex involves three Tim9 and three Tim10 subunits, while the other involves one each of Tim8, Tim9, and Tim13 polypeptides. These complexes deliver the carrier protein to a 300-kDa complex composed of Tim54, Tim22, Tim12, Tim10, and Tim9, bound to the outer face of the inner membrane. The polypeptides Tim8, Tim9, Tim10, Tim12, and Tim13 all

belong to the same gene family, which contains a distinctive duplicated C(N3) C motif reminiscent of a zinc finger (255–258).

### 11.1.5 Mitochondrial Genetics

Each human cell contains hundreds of cytoplasmic mitochondria. The mitochondrial genome encompasses 1000–2000 genes, 37 of which are encoded by the mtDNA while the remainder are dispersed across the nDNA chromosomes. While each cell contains one or two copies of each nDNA gene, the cell contains thousands of copies of the mtDNA. Because the mitochondrial genome encompasses two quite different and semiautonomous information storage and retrieval systems, the genetics of the mitochondrion is quite complex. Genetic phenotypes associated with mitochondrial dysfunction can involve Mendelian inheritance, cytoplasmic mtDNA inheritance, or an interaction between the two (Figure 11-3).

**FIGURE 11-3** Human mitochondrial DNA map showing representative pathogenic and adaptive base substitution mutations. D-loop = control region (CR). Letters around the outside perimeter indicate cognate amino acids of the tRNA genes. Other gene symbols are defined in the text. Arrows followed by continental names and associated letters on the inside of the circle indicate the position of defining polymorphisms of selected region-specific mtDNA lineages. Arrows associated with abbreviations followed by numbers around the outside of the circle indicate representative pathogenic mutations, the number being the nucleotide position of the mutation. Abbreviations: DEAF, deafness; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; LHON, Leber hereditary optic neuropathy; ADPD, Alzheimer and Parkinson disease; MERRF, myoclonic epilepsy and ragged red fiber disease; NARP, neurogenic muscle weakness, ataxia, retinitis pigmentosum; LDYS, LHON + dystonia; PC, prostate cancer. (Data from (1).)

### 11.1.6 Mitochondrial DNA Genes and Genetics

The cytoplasmic location and high copy number of the mitochondria result in the mtDNA having a unique genetics. The mtDNA is a 16,569-nucleotide pair (np), closed circular molecule, located within the mitochondrial matrix. It codes for 13 key polypeptides of OXPHOS as well as the structural RNAs of mitochondrial protein synthesis, including the small (12S) and large (16S) rRNAs as well as 22 transfer RNAs (tRNAs) (see [Figure 11-3](#)). These 22 tRNAs interpret the mitochondrial genetic code through the use of modified wobble codon rules. Certain mitochondrial tRNAs also have modified anticodons that alter the mitochondrial genetic code. In particular, the anticodon of the tryptophan tRNA is modified so that it reads both the normal tryptophan codon (UGG) and the opal stop codon (UGA). Similarly, the methionine tRNA recognizes both AUG and AUA as methionine. Finally, the “universal” arginine codons AGA and AGG are utilized as stop codons in the mtDNA ([259,260](#)).

The 13 polypeptides of the mtDNA include 7 (ND1, 2, 3, 4, 4L, 5, and 6) of the 45 subunits of complex I, 1 (cytochrome *b*) of the 11 subunits of complex III, 3 (COI, II, and III) of the 13 subunits of complex IV, and 2 (ATP6 and 8) of the 16 subunits of complex V. The mtDNA also contains an approximately 1121-np control region that encompasses the heavy (H)- and light (L)-strand promoters ( $P_H$  and  $P_L$ ) and the H-strand origin of replication ( $O_H$ ). The L-strand origin ( $O_L$ ) is located on the other side of the circle in a cluster of five tRNA genes (WANCY).

The most widely accepted model for mtDNA replication is that DNA replication initiates at  $O_H$  using an RNA primer generated from the L-strand transcript. The L-strand transcript initiates at the adjacent  $P_L$  and is cleaved by the nuclear-encoded mitochondrial RNase processing RNase at runs of G nucleotides in the conserved sequence blocks CSBIII, CSBII, and CSBI, primarily after CSBI ([261–264](#)). The resulting 3'-OH is utilized by DNA polymerase  $\gamma$  as a primer to synthesize a 7S DNA. The 7S DNA ends at the termination associated sequence at the end of the control region. The termination associated sequence binds to a specific factor that may regulate this replication pause site ([265](#)). This newly synthesized region of the H-strand displaces the parental H-strand to create the displacement loop (D-loop) ([265,266](#)). The 7S DNA is subsequently utilized as a primer to synthesize a new H-strand. From the 7S DNA, H-strand synthesis proceeds two-thirds of the way around the mtDNA, displacing the parental H-strand until it reaches the  $O_L$ . Once exposed on the displaced H-strand,  $O_L$  folds into a stem-loop structure and L-strand synthesis initiates and proceeds back along the H-strand template. Consequently, mtDNA replication is bidirectional but

asynchronous ([267](#)). However, recent studies have suggested that the mtDNA may also replicate bidirectionally and thus symmetrically from alternative origins ([268–270](#)).

mtDNA transcription initiates from the two promoters in the control region, one for each strand:  $P_L$  and  $P_H$ .  $P_H$  is responsible for transcribing the 2 rRNA genes, 13 tRNA genes, and 12 of the protein coding genes.  $P_L$  transcribes the ND6 protein gene and nine tRNAs, and also generates the primers for H-strand replication at  $O_H$  ([11](#)). Both promoters are associated with a binding site for a nuclear-encoded mitochondrial transcription factor (Tfam). Tfam is a high-mobility-group DNA-binding protein with two DNA-binding domains and a carboxy-terminal tail essential for transcription ([271–274](#)). It binds with higher affinity to  $P_L$  than  $P_H$ , consistent with their relative transcription frequencies ([275,276](#)). Tfam also binds with a 40- to 50-base periodicity throughout the D-loop, with CSBII and CSBIII being unbound and CSBI being strongly bound. The Tfam phasing downstream from CSBI on the H-strand DNA corresponds to DNA synthesis initiation sites, suggesting that Tfam may help define the transitions between RNA and DNA ([277](#)).

Transcription from both promoters proceeds around the mtDNA circle, creating a polycistronic RNA. The tRNA genes, which punctuate the larger rRNA and mRNA sequences, then fold within the transcript and are cleaved out by an RNaseP-like activity. The freed mRNAs and rRNAs are post-transcriptionally polyadenylated; and the tRNAs are modified and the 3' terminal CCA is added ([278–281](#)).

The rRNAs are present in about a 50:1 ratio with the mRNAs. This differential transcription is accomplished in part by a transcriptional terminator (5'-TGGCAGAGCCCCGG-3') located within the tRNA<sup>Leu(UUR)</sup> gene, immediately downstream from the 16S rRNAs in the direction of H-strand transcription from  $P_H$ . This terminator is bidirectional, thus accounting for the reduction in read-through of the H-strand promoter as well as the termination of the L-strand transcripts prior to its reaching the rRNA genes ([275,282,283](#)).

The mtDNA mRNAs are translated on mitochondrial 55S ribosomes (mitoribosomes) composed of a large 39S and small 28S subunit. These ribosomes have a smaller amount of rRNA than bacterial or eukaryotic ribosomes but a larger number of ribosomal proteins ([284–286](#)). mtDNAs mRNAs lack the traditional Shine-Dalgarno sequence for ribosome binding and generally start with the initiation codon at the 5' end. Translation is thought to initiate with the binding of the small subunit to a 40-base region of the mRNA. The ribosome then moves back to the 5' end to initiate translation. The mRNA has been proposed to wrap around the ribosome, thus limiting polysome formation ([259,287](#)).

The mitoribosomes are sensitive to the bacterial ribosome inhibitor chloramphenicol (CAP), but resistant to the cytosolic 80S ribosome inhibitors cycloheximide and emetine. They are also relatively insensitive to the aminoglycoside antibiotics such as streptomycin and gentamycin except in individuals harboring certain 12S rRNA mutants which markedly increase aminoglycoside sensitivity (260).

### 11.1.7 Mitochondria Are Semiautonomous

Because the mitochondria retain their own self-replicating genome and associated replication, transcription, and translation systems, they behave as semiautonomous organisms within the human cell cytoplasm. This was first demonstrated through studies of cultured mammalian cells selected for resistance to the mitochondrial ribosome inhibitor CAP. CAP-resistant (CAP<sup>R</sup>) cells were enucleated by treatment with cytochalasin B to disaggregate the cytoskeleton and suspension in a centrifugal field to pull the dense nucleus from the cells, thus creating plasma membrane-bound nuclear (karyoplast) and cytoplasmic (cytoplast) fragments, the latter encapsulating the mitochondria and mtDNAs. The CAP<sup>R</sup> cytoplasts were then fused to CAP-sensitive (CAP<sup>S</sup>) cells and the resulting cytoplasmic hybrids, or cybrids, were shown to acquire the CAP<sup>R</sup> genotype and phenotype (288–290). By this cybrid transfer procedure, CAP resistance could be transferred from cell to cell and was later linked to restriction fragment length polymorphisms in the mtDNA (291) as well as to mtDNA-encoded protein polymorphisms (56). Subsequent sequencing of CAP<sup>R</sup> mtDNAs revealed that CAP resistance was due to single nucleotide changes in the peptidyl transferase region of the 16S rRNA (MTRNR1) near the 3' end: a T-to-C transition at np 2991 or a C-to-A transversion at np 2939 (292).

Cybrid transfer of mtDNAs can be facilitated by removing the mtDNAs of the recipient cell prior to fusion. This can be accomplished by fusing the cytoplast to a karyoplast to yield a reconstituted cell (293), by destroying the resident mitochondria by treating the recipient cell with the mitochondrial poison rhodamine-6G (294,295), or by curing the recipient cell of its resident mtDNAs by growth in the mtDNA replication inhibitor ethidium bromide (296). Cells that have been cured of their resident mtDNAs using ethidium bromide are designated  $\rho^0$  cells. They become auxotrophic for uridine (297) and require high glucose levels for energy and pyruvate to maintain redox balance through oxidation of NADH + H<sup>+</sup> via lactate dehydrogenase to give lactate (298). The  $\rho^0$  recipient cells have provided a powerful tool for studying the biochemical basis of mtDNA disease mutations by permitting demonstration that a specific biochemical defect in a patient cell line can be transferred along with the patient mtDNAs to a  $\rho^0$  cell having a different set of nuclear genes (298–302).

### 11.1.8 Mitochondrial DNAs Are Maternally Inherited

The human mtDNA is strictly maternally inherited (303,304). This is due in large measure to the fact that the mammalian egg contains about 100,000 mitochondria and mtDNAs, while the sperm contains on the order of 100 mtDNAs (305,306). The sperm mtDNAs are contributed to the zygote at fertilization and will persist in interspecific crosses (307). However, in intraspecific crosses, the sperm mitochondria are selectively eliminated (308). This has been correlated with the discovery that the sperm mitochondria prohibiting protein are decorated with ubiquitin, which appears to mark them for degradation on entrance into the oocytes (309,310). This destruction of sperm mitochondria and mtDNAs can also be demonstrated by injecting sperm into  $\rho^0$  somatic cells (311).

### 11.1.9 mtDNA's High Mutation Rate

The mtDNA mutation rate is much higher than that of nuclear genes (312). Comparison of the sequence diversity of mtDNA and nDNA genes that function in the same enzymes indicates that mtDNA genes evolve about 10–17 times faster than nDNA genes (181,202,313). However, the mtDNA genes are also highly conserved and critical for life. Therefore, a high mtDNA mutation rate would be expected to create a high genetic load which would ultimately result in the decline in the fecundity of the species. This problem is resolved in that the mammalian ovary has a selective system that eliminates the proto-oocytes with the most severe mitochondrial defects prior to ovulation (314,315). This pre-fertilization selection is possible for the mitochondrion since respiratory defects are manifest at the cellular level so selection can occur before the generation of a complete individual. As a result, mtDNA variants that mildly perturb mitochondrial bioenergetics are continuously being introduced into the population. While most of these still cause significant mitochondrial defects and disease (1), a subset of the variants can be beneficial in certain environments and can become enriched in that context through the action of adaptive selection. Hence, the high mutation rate, tempered by intra-ovarian selection provides a power system for permitting intra-specific adaptation to changing environments. By contrast, since anatomical mutations can only be presented to selection after the individual has been conceived and gone through development, all anatomical mutations are introduced into the population. Hence, nDNA anatomical mutations impart a high genetic load and, thus, nDNA mutation rates must be kept low (316). Therefore, the high mtDNA mutation rate, coupled to pre-fertilization selection, means that the mtDNA is constantly generating potentially adaptive mutations; so mtDNA mutations provide the genetic diversity that allows individuals within a species to adapt to changing environmental conditions (317).

Still, some of the mtDNA mutations are deleterious in particular environmental contexts. New female germline mtDNA mutations can either result in base substitution or rearrangement mutations ([www.mitomap.org](http://www.mitomap.org)) (318). Rearrangement mutations and base substitutions that disrupt an important mitochondrial function are deleterious and are removed by natural selection as disease. Base substitution mutations could also be neutral, which can be retained or lost in the general population by genetic drift, or be advantageous in particular environments, where they can become established in the specific populations by adaptive selection. The high mtDNA mutation rate might explain why animals retain mtDNA recombination (319), while prohibiting inter-mtDNA lineage recombination by strict maternal inheritance. Current evidence suggests that the 13 mtDNA polypeptides are critical for OXPHOS electron and proton transport. Since all of the components of OXPHOS must work together to provide an integrated energy system, strict maternal inheritance ensures that each new mutation is added sequentially to the pre-existing optimized mtDNA genotype. If it is deleterious to mitochondrial energetics, the mutation will be eliminated by selection. However, if advantageous, it may permit the population to survive and expand. Since the high mtDNA mutation rate would frequently result in deleterious mutations occurring on the same mtDNA as advantageous mutations, good mutations would be lost with the bad. The presence of recombination within the female germline would randomly distribute the deleterious and advantageous mtDNA mutations so that they could segregate independently (319).

New mutations in the mtDNA not only accumulate along the female germline, they also arise as mtDNAs replicate within the cells of the body, particularly in the post-mitotic tissues, where the absence of cytokinesis inhibits the segregation of the mutant mtDNAs (320,321). Thus, human mitochondrial genetics involves the interaction between the systemic deleterious, neutral, and adaptive germline mutations and the age-related accumulation of somatic mtDNA mutations.

### 11.1.10 Heteroplasmy and Replicative Segregation

When a mutation arises in a cellular mtDNA, it creates a mixed intracellular population of mutant and normal molecules known as heteroplasmy. When a cell divides, it is a matter of chance whether the mutant mtDNAs will be partitioned into one daughter cell or another. Thus, over time, the percentage of mutant mtDNAs in different cell lineages can drift toward either pure mutant or normal (homoplasmy), a process known as replicative segregation. In somatic cell hybrids between transformed human cell lines, the direction of segregation appears to be random (322). However, in crosses between HeLa cells and either diploid fibroblasts (323–325) or lymphoblastoid cell lines (290), the HeLa mtDNAs are

preferentially lost, even when selected for using CAP resistance. The reason for this directional replicative segregation is unknown. However, it may have clinical significance since it has been reported that, in five of seven  $\rho^0$  cybrids heteroplasmic for the pathogenic tRNA mutation MTTL1\*MELAS3243G (326), the wild-type mtDNAs were selectively lost and the mutant mtDNAs preferentially retained (327). This directional segregation may also involve nuclear genes. In another study, using the same osteosarcoma 143B TK<sup>-</sup>  $\rho^0$  recipient cell, 1 of 14 heteroplasmic cybrids segregated toward mutant mtDNAs, while the others remained stable. By contrast, with a different  $\rho^0$  recipient cell (A549, B2), 5 of 25 heteroplasmic cybrids segregated to wild-type mtDNAs (328). Preferential growth of cells with wild-type mtDNAs has also been observed during cybrid clone isolation (329) and in propagation of heteroplasmic fibroblasts (330). Hence, the rules governing the directionality of mtDNA segregation and the factors that influence it still remain to be elucidated.

### 11.1.11 Threshold Expression

As a result of the energy anatomy of the body, the different tissues and organs rely on mitochondrial energy generation to different extents. This has been well established through studies of respiratory inhibitor toxicity in mammals, including primates. Acute respiratory toxicity can result in unconsciousness, while chronic toxicity can result in optic atrophy, basal ganglia degeneration, and cardiac and renal failure (331). Studies on maternal pedigrees harboring heteroplasmic mtDNA mutations indicate that, as the percentage of mutant mtDNAs increases, energy production declines. Ultimately, the percentage of mutant mtDNAs crosses a threshold resulting in clinical manifestations. Observations from many cases now indicate that the bioenergetic expression thresholds for human organs are, in decreasing order, the central nervous system, heart and skeletal muscle, renal system, endocrine system, and liver (5,6,332,333). The pathophysiologic basis of these organ thresholds is still unclear. However, current data suggest that three major processes of the mitochondria are relevant: decline in energy production, increase in ROS production, and initiation of apoptosis, which eventually removes sufficient cells from the organ that the organ malfunctions, resulting in disease.

While the mechanism for threshold expression may vary in different contexts, genetic studies have repeatedly shown that the difference in mitochondrial function between normal and defective cells can be quite small. In somatic cell hybrids between CAP<sup>R</sup> and CAP<sup>S</sup> cells, as little as 10% CAP<sup>R</sup> mtDNAs are required for the cell to survive and grow in CAP (322). Similarly, in diseases resulting from mtDNA tRNA mutations, the percentage of mutant mtDNAs must be high before the biochemical and clinical expression threshold is exceeded. In families

harboring the MTTK\*MERRF8344G mutation (5), it has been observed that individuals in the 20- to 40-year age range require at least 85% mutant mtDNAs for symptoms to appear (5,6,334). This is consistent with data from cultured somatic cells in which the percentage of MTTK\*MERRF8344G or MTTLI\*MELAS3243G mutant mtDNAs must exceed 90% before both protein synthesis and O<sub>2</sub> consumption decline (335).

Part of the threshold effect is explained by “respiratory control theory.” It has been established that certain of the respiratory complexes can be strongly inhibited without reducing the respiration rate. This results from the fact that the various respiratory complexes have different degrees of excess respiratory capacity, relative to the overall electron flux rate through the respiratory chain. For example, complex I activity must be reduced by more than 70% before oxygen consumption or ATP production is perturbed (300,336,337). Hence, a mutation in an mtDNA complex I subunit would have to increase to a relatively high percentage of the cellular mtDNAs before it would significantly impede mitochondrial respiration and energy production.

### 11.1.12 Mitochondrial Dynamics and mtDNA Complementation

The mitochondria are high dynamic organelles undergoing repeated rounds of fission and fusion. This dynamic process can be linked to the activation of the mtPTP, apoptosis, and the turnover of mitochondrial by autophagy (mitophagy). The first demonstration the mitochondria must fuse came from a complementation experiment between two different mitochondrial when mixed in somatic cell hybrids. Pairs of human cells were fused together in which one harbored an mtDNA in which the mtDNA CAP<sup>R</sup> mutation was linked to an ND3 protein polymorphism (MV-1) and the other cell carried a CAP<sup>S</sup> mtDNA linked to an ND3 allele with a different electrophoretic mobility (MV-2). When the mitochondrial translation products of the hybrids were selectively labeled by growth in <sup>35</sup>S-methionine together with emetine to block cytosolic protein synthesis, both MV-1 and MV-2 were synthesized in proportion to the percentage of the two mtDNAs. Moreover, both proteins continued to be labeled when the hybrids were grown in <sup>35</sup>S-methionine in the presence of both emetine and CAP. This revealed that the CAP<sup>R</sup> mtDNA ribosomes were able to translate the ND3 mRNAs from the CAP<sup>S</sup> mtDNAs in *trans*. Hence, the ribosomes of the CAP<sup>R</sup> mtDNA must occupy the same mitochondrial compartment as the CAP<sup>S</sup> mtDNA-linked MV-2 mRNAs demonstrating the mitochondria of the two parental cells must have coalesced following cell fusion (56).

Intracellular mtDNA complementation has also been demonstrated in cells heteroplasmic for the pathogenic tRNA mutation MTTLI\*MERRF8344G. In cybrids derived from heteroplasmic cells, as little as 10% of normal

mtDNAs were able to restore oxygen consumption and mitochondrial protein synthesis. However, when essentially homoplasmic MTTLI\*MELAS3243G genomes were mixed with homoplasmic MTTK\*MERRF8344G genomes by two-step cybrid selection, complementation was not observed for either oxygen consumption or mitochondrial translation (335).

Mitochondrial complementation is now understood at the cellular level via the processes of fission and fusion. A number of the genes important in these processes have been cloned. Fusion permits the complementation of defects between different mitochondria and mtDNAs (338). Mitochondrial fusion is mediated by mitofusin 1 and 2 (Mfn1 and Mfn2) and OPA1 (optic atrophy 1 protein) while fission is mediated by Fis1 and Drp1 (dynamin-related protein 1) (339). Mitochondrial fusion mediated by Mfn1 and Mfn2 is modulated by the formation of high-molecular-weight GTP-dependent complexes (340), and the genetic inactivation of both Mfn1 and Mfn2 leads to severe mitochondrial defects, including poor growth, heterogeneity in mitochondrial membrane potential, decreased respiration (341), and increased apoptosis (342).

Fission is essential to separate mitochondria for transport throughout large cells like neurons (338,339,343,344). Fission is also modulated by the Bax-Bcl-2 family of proteins (345,346) and permits isolation of mutant nucleoids in mitochondrial vesicles where the mtDNA can be expressed and if defective result in a reduced membrane potential signaling removal by mitochondrial autophagy, mitophagy.

Mitophagy is initiated by the mitochondrial membrane protein PINK1 which is degraded in normal mitochondrial but stabilized in the mitochondrial outer membrane in mitochondria with lowered membrane potential (347). PINK1 phosphorylates the cytosolic protein parkin, attaching it to the mitochondrion (348) where it ubiquitinates mitofusins 1 and 2 (349) and activates a mitochondrial ubiquitin-proteasome system (350). The ubiquitinated mitofusins attract the adaptor protein p62/SQSTM1 (351) which recruits the mitophagy apparatus including the microtubule-associated protein 1 light chain 3 (LC3) protein and Atg autophagy proteins to engulf the mitochondria in an autophagosome preparatory to degradation (345,346,352–354).

### 11.1.13 mtDNA Recombination

It is now clear that mtDNAs within a mitochondrion can recombine. While recombination in cultured mammalian cells is infrequent (355), evidence for the interconversion of duplicated and deleted mtDNA molecules with the same breakpoint junction within patient tissues has suggested that intramolecular recombination may be relatively frequent (356). Analysis of mouse L cell lines has revealed that various sublines of LA9 cells harbored functional mtDNA mutations present at high

percentages of heteroplasmy. Analysis of the mtDNAs of these cell lines has revealed that different cell lines have different combinations of the same mutations. A reconstruction of the chain of events that led to the extant cell line mtDNA genotypes has revealed that the various combinations of alleles must have arisen by at least three independent recombination events (319).

While intracellular mtDNA recombination has been confirmed, extensive analysis of human mtDNAs from populations containing multiple different mtDNA lineages has failed to reveal a bona fide example of recombination between two very different mtDNA lineages (357). Consequently, the mtDNA haplotypes from different populations exhibit a very high degree of linkage disequilibrium throughout the mtDNA (358–361). While some analyses have purported to demonstrate the loss of linkage disequilibrium within mtDNA lineages (362), subsequent analysis has failed to confirm these conclusions (363–365). Since intracellular recombination does occur, the absence of recombination between mtDNA lineages implies that the mixing of mtDNAs between lineages is prohibited. This conclusion has been confirmed by the demonstration that sperm mitochondrial are ubiquitinated (366). These mitochondrial are then degraded by mitophagy on entry into the oocyte (366).

#### 11.1.14 Energy Anatomy and Mitochondrial Seasonal Metabolism

To understand the functional significance of the deleterious and adaptive mtDNA mutations, it is necessary to understand the energetic functions of the different human tissues, the human energy anatomy. Tissues rely on mitochondrial energy to different extents, which markedly affects their responses to mutations in mitochondrial genes. Human and mammalian organs can be divided into four energetic categories:

- The *energy-utilization* tissues, including the brain, which burn carbohydrates and ketone bodies; the skeletal muscle, which metabolizes carbohydrates and fats; the heart, which burns primarily fat; and the kidney
- The *energy-storage* tissues, including white adipose tissue (WAT) for energy storage and brown adipose tissue (BAT) for thermal regulation
- The *energy-homeostasis* tissue: the liver, which maintains serum glucose levels
- The *energy-sensing* tissues: the alpha and beta cells of the pancreatic islets of Langerhans, which monitor the availability of plant calories via serum glucose levels and regulate energy metabolism accordingly, shifting between glycolysis and OXPHOS

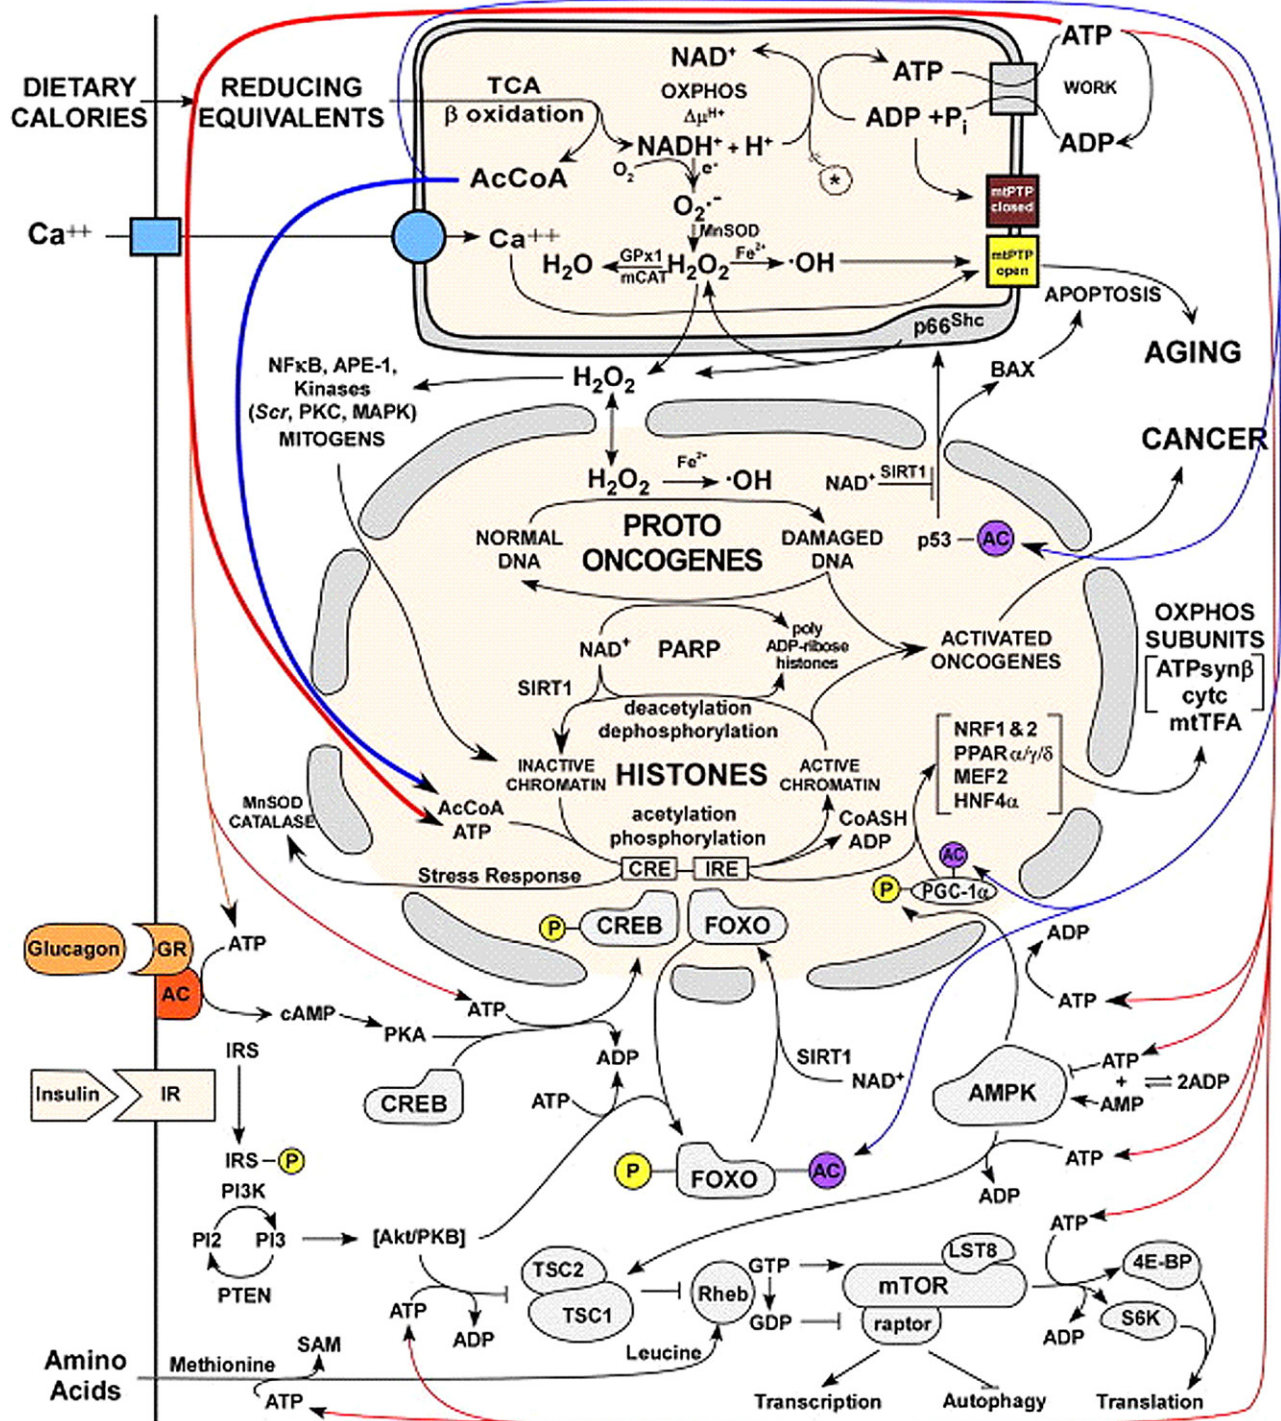

All of these tissues interact to coordinate the utilization and storage of energy, based on the availability of calories in the environment. For our hunter–gatherer

ancestors, the primary variation in available dietary calories was due to the cyclic growing seasons of edible plants caused by either warm versus cold or wet versus dry seasons. During the growing season, plants convert the sun's energy into glucose, which the plants store as starch. When humans ingest these plant tissues, the concentration of glucose in their blood rises.

The elevated serum glucose is detected by the energy-sensing pancreatic beta cells, which respond by secreting insulin into the blood stream. The insulin signal then informs the energy-utilizing tissues to downregulate mitochondrial energy utilization, thus relying more heavily on glycolysis, and to store the excess calories as high-energy fat in the WAT and BAT. As the growing season of the plants ends, the availability of plant carbohydrate calories declines. This results in the decline of animal blood glucose levels. In response, the pancreatic beta cells reduce insulin production and the pancreatic alpha cells increase glucagon production. These hormonal changes signal the upregulation of mitochondrial OXPHOS in the energy-utilizing cells and the mobilization of the fats stored in the WAT to fuel mitochondrial OXPHOS in the energy-utilizing tissues. Low blood glucose also stimulates the liver to synthesize glucose to maintain the basal blood sugar level, which is particularly critical for brain metabolism.

When blood glucose is high and the beta cells secrete insulin, the insulin binds to insulin receptors on target cells throughout the body. Insulin binding to the receptors activates the receptor tyrosine protein kinase to phosphorylate insulin receptor substrates. These activate phosphatidylinositol-3-kinase (PI3K), which phosphorylates phosphatidylinositol 2-phosphate to phosphatidylinositol 3-phosphate (PI3). PI3 then activates the AKT 1/2 kinases (protein kinase B, PKB), which phosphorylate the FOXO forkhead transcription factors FOXO1, FOXO3A, and FOXO4 in the target tissues. Phosphorylation of the FOXOs results in their transport out of the nucleus and the transcriptional inactivation of genes whose promoters contain insulin response elements (IRE) (367,368). The FOXOs can also be removed from the nucleus by acetylation via Cbp or p300 (367) and reactivated by deacetylation via the NAD<sup>+</sup>-dependent SIRT1 (sirtuin 1) (369).

When blood sugar is low, insulin levels decline, the insulin receptor shuts down, AKT 1/2 is inactive, and the FOXOs become dephosphorylated. The unphosphorylated FOXOs enter the nucleus, bind to the IREs, and upregulate transcription of the associated genes. Low blood glucose also stimulates the pancreatic alpha cells to secrete glucagon, which binds to the glucagon receptors in target cells. This stimulates the production of cyclic AMP (cAMP), which activates protein kinase A (PKA). PKA phosphorylates and activates the cAMP response element binding protein (CREB), which activates transcription of genes harboring a cAMP response element (CRE) (370) (Figure 11-4).

**FIGURE 11-4** Mitochondrial regulation of energy flow and its impact on the cellular epigenome and signal transduction pathways mediated by high energy mitochondrial intermediates. Energy is derived from reducing equivalents contained in dietary calories. Carbohydrates and fatty acids are converted to acetyl-CoA, NADH+H<sup>+</sup> and FADH<sub>2</sub> and these are oxidized with oxygen within the mitochondrion. The reducing equivalents of NADH+H<sup>+</sup> and FADH<sub>2</sub> are oxidized by the mitochondrial ETC to generate the mitochondrial electrochemical gradient ( $\Delta P = \Delta \Psi + \Delta \mu^{H^+}$ ) and  $\Delta P$  is utilized by the ATP synthase to generate ATP. Acetyl-CoA and ATP are exported from the mitochondrion and these high energy intermediates are used to modify the proteins chromatin and the cellular signal transduction pathways, thus coupling mitochondrial energy flux to the regulation of the epigenome. The source of the available calories modulates the systems by which the calories are processed based on signals from the pancreatic islets of Langerhans. High carbohydrates activate the  $\beta$  cells to secrete insulin. This binds to the cellular insulin receptors, which act through the PI3K-PTEN-Akt-FOXO pathway to shift energy metabolism away from oxidation and toward glycolysis. By contrast, low carbohydrate diets activate the  $\alpha$  cells to secrete glucagon. This binds to the glucagon receptors which act through the cAMP-PKA-CREB pathway to shift energy metabolism toward oxidative phosphorylation, in significant measure through the induction of PGC-1 $\alpha$ . SIRT1 fine-tunes the interrelationship between energy metabolism and apoptosis through the deacetylation of PGC-1 $\alpha$ , p53, and the histone proteins. Caloric overload or inhibition of OXPHOS perturbs the cellular mitochondrial energetic balance resulting in increased ROS. The increased ROS and decreased mitochondrial energy output sensitizes the mtP, ultimately driving the cell to apoptotic death. The increased ROS also diffuses into the nucleus as H<sub>2</sub>O<sub>2</sub> where it can mutate and activate proto-oncogenes (initiation) and can interact with NF- $\kappa$ B, APE-1 and various kinases to initiate cell division (promotion) leading to neoplastic transformation (cancer). Abbreviations: PARP, poly ADP-ribose polymerase; SIRT1 is the mammalian homolog to Sir2; FOXO3, the most ubiquitous mammalian forkhead transcription factor; P, a phosphorylated protein; Ac, an acetylated protein; IL, insulin ligand; ILL, insulin-like ligand; IR, insulin receptor; ILR, insulin-like growth factor receptor; IRE, insulin response element; PI3K, the PI3 kinase; PI2, the membrane-bound phosphatidylinositol diphosphate; PI3, membrane-bound phosphatidylinositol triphosphate; AKT 1/2, the AKT kinases; ATPsyn $\beta$ , ATP synthase  $\beta$  subunit; cytc, cytochrome c. (Refs. (1,2,13).)

The FOXOs and CREB regulate numerous genes through the IRE and CRE *cis* elements. The promoter of the peroxisome proliferation-activated receptor- $\gamma$  (PPAR- $\gamma$ ) coactivator 1 $\alpha$  (PGC-1 $\alpha$ ) gene contains three IREs that bind unphosphorylated and deacetylated FOXO1. It also contains one CRE that binds phosphorylated CREB (370). PGC-1 $\alpha$ , together with its companion genes PGC-1 $\beta$  (PERC) and PGC-related coactivator (PRC), are transcriptional coactivators that regulate genes for mitochondrial biogenesis, thermogenesis, and fatty acid oxidation (371,372).

The PGC-1 family of transcriptional coactivators interacts with a broad spectrum of tissue-specific transcription factors. This provides the tissue-specific response to the generalized insulin and glucagon hormonal signals. In the energy-utilizing muscle cells (C2C12), PGC-1 $\alpha$  induces mitochondrial biogenesis and UCP-2, acting through the nuclear respiratory factors 1 and 2 (NRF1 and NRF2) (373). NRF1 and NRF2, in turn, activate the transcription of a wide range of nDNA encoded mitochondrial genes, including components of OXPHOS such as the ATPsyn $\beta$  subunit (ATPsyn $\beta$ ) and cytochrome *c* and the mtTFA, which regulates mtDNA transcription (371,372). In muscle, PGC-1 induces mitochondrial biogenesis through the interaction with NRF1, PPAR- $\beta$ , PPAR- $\delta$ , MEF2, ERR2 (estrogen-related receptor 2), HDAC5, and Gabpa/b (GA-repeat binding protein) (374–377). In the heart, PGC-1 $\alpha$  interacts with PPAR- $\alpha$  and NRF1 (375,378). In the brain, the transcriptional partners of PGC-1 $\alpha$  have not yet been identified (379).

In the energy-storage tissue for thermal regulation (BAT), cold stress activates the cAMP-mediated  $\beta$ -adrenergic receptors to upregulate PGC-1 $\alpha$ . PGC-1 $\alpha$  in turn interacts with PPAR- $\gamma$ , PPAR- $\alpha$ , and the thyroid hormone receptor to induce mitochondrial biogenesis and UCP-1 (373,375). The induction of UCP-1 creates a proton channel through the mitochondrial inner membrane, uncoupling OXPHOS. This causes the rapid burning of the stored fats in BAT, generating heat to maintain body temperature (380).

In the energy-storage tissue for fueling work (WAT), PGC-1 $\alpha$  in 3T3-L1 preadipocytes interacts with PPAR- $\alpha$  to stimulate fatty acid oxidation, including induction of the medium-chain acyl CoA dehydrogenase (MCAD) (381). Finally, in the energy-homeostasis tissue (liver), PGC-1 $\alpha$  interacts with FOXO1, hepatocyte nuclear factor-4 $\alpha$  (HNF-4 $\alpha$ ), and the glucocorticoid receptor to induce gluconeogenesis enzymes, including phosphoenolpyruvate carboxylase (PEPCK) and glucose-6-phosphatase (G6Pase), to maintain basal blood glucose levels (375,382–384).

PGC-1 $\beta$  is abundantly expressed in BAT, heart, and kidney and skeletal muscle but also in stomach and in WAT. In 3T3-L1 preadipocytes, PGC-1 $\beta$  is inducible, though PGC-1 $\alpha$  is not, and PGC-1 $\beta$  then interacts with the ERRs to induce MCAD and fatty acid oxidation (385). Thus, both insulin through the FOXOs and glucagon through cAMP modulate mitochondrial energy metabolism in response to the availability of carbohydrates via the regulation of members of the PGC-1 coactivator family.

Mitochondrial energy metabolism is further modulated by PGC-1 $\alpha$  through deacetylation by SIRT1. PC12 cells that overexpress SIRT1 experience a 25% reduction in oxygen utilization (386). Hepatocytes that overexpress SIRT1 induce the gluconeogenesis genes *PEPCK* and *G6Pase* via interaction between PGC-1 $\alpha$  and HNF-4 $\alpha$  (383). Furthermore, on caloric restriction, the SIRT1 in fat cells binds to the nuclear receptor corepressor, blocking its interaction with PPAR- $\gamma$ . This inhibits fat storage and enhances fat mobilization (387,388).

### 11.1.15 Mitochondrial Stress Response Pathways

In addition to responding to differences in the availability and nature of environmental calories to the whole organism, the cell and its mitochondria must respond to the mitochondrial production of ROS with respect to oxidative damage, induction of apoptosis, and signal transduction. While it is well known that mitochondrial ROS damages cellular macromolecules, including mtDNA and nDNA, and can result in apoptosis, it is less well known that mitochondrially generated H<sub>2</sub>O<sub>2</sub> is a vital component in regulating cellular mitosis.

Mitochondrial ROS acts as a mitogen through its interaction with a variety of cytosolic and nuclear signal transduction pathways. Excess mitochondrial H<sub>2</sub>O<sub>2</sub> diffuses out of the mitochondrion and into the cytosol and the nucleus, where it interacts with NF- $\kappa$ B, apurinic/apyrimidinic endonuclease-1 (APE-1), Fos, Jun, and tyrosine kinases (Src kinase, protein kinase C, mitogen-activated protein kinase, and receptor tyrosine kinases) (389). The dual-functional APE-1 is also involved in the redox regulation of Fos, Jun, NF- $\kappa$ B, PAX, hypoxia-inducible factor 1 $\alpha$  (HIF-1 $\alpha$ ), and p53 (390,391).

The activation of the tyrosine kinases and/or Ras activates PI3K, which in turn activates the *Akt*/PKB kinases. The *Akt*/PKB kinases also promote the binding of the hexokinase II to mitochondrial voltage-dependent anion channel, thus coupling mitochondrial ATP production to driving glycolysis. The activated *Akt*/PKB kinases also phosphorylate the FOXO transcription factors. The phosphorylation of the FOXOs removes them from the nucleus so that they do not bind the IREs in gene promoters, including the mitochondrial MnSOD gene and PGC-1 $\alpha$ , thus downregulating mitochondrial antioxidant defenses and mitochondrial OXPHOS. As a consequence, the cells switch from more oxidative to more glycolytic, further compensating for the possible effects of an overabundance of mitochondria.

The mitochondria also contain the p66<sup>Shc</sup> protein attached to the outside of the mitochondrial inner membrane. In response to stress stimuli, p66<sup>Shc</sup> collects electrons directly from cytochrome *c* and passes them to O<sub>2</sub> to generate H<sub>2</sub>O<sub>2</sub> (392). Thus, stress can also act through mitochondrial H<sub>2</sub>O<sub>2</sub> to drive cellular replication.

The mitochondrial modulation of nuclear transcription and replication can also be enhanced by the

expression of cytosolic NADPH oxidases. NADPH oxidases reduce  $O_2$  to generate superoxide anion in the cytosol. The best characterized of the NADPH oxidases is the macrophage “oxidative burst” complex involved in generating the  $O_2^-$  to kill engulfed microorganisms. However, an additional NADPH oxidase, Mox1, is a homolog of the gp91phox catalytic subunit of the phagocyte NADP oxidase. MoxX1-generated  $O_2$  increases mitotic rate, cell transformation, and tumorigenicity when Mox1 is overexpressed in NIH3T3 cells (393). This mitogenic activity of Mox1 is neutralized by overexpression of catalase, indicating that the cell growth signal must be  $H_2O_2$  (394). Hence, the modulation of cellular proliferation through  $H_2O_2$  can be modulated by both mitochondrial number and function and also by expression of the nDNA NADH oxidases.

While at low levels mitochondrial  $H_2O_2$  can serve as a signaling system to the nucleus, at high levels the concentration of  $H_2O_2$  in the nucleus continues to accumulate, where it can be converted to hydroxyl radicals, which will then damage the nDNA. Damage to the nDNA will then activate the nDNA repair system, including poly(ADP-ribose) polymerase (PARP). PARP converts the nuclear  $NAD^+$  into poly(ADP-ribose) linked to nuclear proteins, thus depleting nuclear  $NAD^+$ . The nuclear  $NAD^+$  level is further depleted by its reduction to NADH as a consequence of the inhibition of the mitochondrial ETC. Depletion of nuclear  $NAD^+$  deprives the protein deacetylase SIRT1 of its obligatory substrate  $NAD^+$ , thus inhibiting deacetylation of histones, the FOXOs, and p53. The increased acetylation of p53 increases its activity, thus driving apoptosis.

PARP is a nDNA enzyme that is activated by fragments of DNA resulting from DNA damage. Utilizing  $NAD^+$  as a substrate, it transfers 50 or more ADP-ribose moieties to nuclear proteins such as histones and PARP itself. Massive DNA damage results in excessive activation of PARP, which leads to the depletion of  $NAD^+$ . The resynthesis of  $NAD^+$  from ATP then markedly depletes cellular ATP, leading to death (395). Mice in which the PARP gene has been genetically inactivated show remarkable resistance to cellular stress such as cerebral ischemia (stroke) (396,397) and streptozotocin-induced diabetes (398).

SIRT1 also uses  $NAD^+$  as a cofactor to diacetylate proteins, including FOXOs, p53, and the histones. Diacetylated histones keep silent genes, such as proto-oncogenes, turned off (399). Degradation of  $NAD^+$  would inactivate SIRT1, permit histones to be acetylated and silent genes to be illegitimately expressed, further driving cell division.

The nuclear protein p53 can initiate programmed cell death and is activated by DNA damage and by acetylation. The p53 apoptotic pathway acts through mitochondrial cytochrome c release and requires the intervention of the proapoptotic protein Bax (400). The stress activation

of p66<sup>Shc</sup> can also increase  $H_2O_2$  and contribute to driving cells into apoptosis (392).

The regulation of the nuclear-cytosolic functions by mitochondrial ROS is further modulated by a series of other short- and long-lived small regulatory molecules. One of these is short half-life nitric oxide (NO). NO is generated from arginine by nitric oxide synthase (NOS). There are three cytosolic NOS isoforms: neuronal NOS (nNOS), inducible NOS (iNOS), and endothelial NOS (eNOS), which is expressed in activated macrophages. NOS has recognition sites for calmodulin, NADPH, FAD, and FMN and uses heme and tetrahydrobiopterin as oxidation–reduction cofactors. nNOS is tethered to N-methyl-D-aspartate (NMDA) receptors in neurons by the PSD-95 protein. Hence, when NMDA receptors are activated by glutamate, permitting  $Ca^{2+}$  to flow into the cytosol, this immediately activates nNOS via calmodulin (395,401). The NO generated by NOS can react with superoxide anion ( $O_2^-$ ) to give the highly reactive peroxynitrite anion ( $ONOO^-$ ). This can be protonated to give peroxynitrous acid ( $ONOOH$ ) (402).

The mitochondrion has its own mitochondria-specific NOS, which may be attached to the mitochondrial inner membrane (403,404). Mitochondrial NO has been shown to reversibly inhibit complex IV (COX), causing a reduction in  $\Delta p$  and  $Ca^{2+}$  release from the mitochondria (405). Mitochondrial NO can also react with  $O_2^-$  to generate  $ONOO^-$ , which can inactivate mitochondrial creatine phosphokinase (406), activate the mitochondrial release cytochrome c (407), inhibit other respiratory complexes (408), and possibly activate PARP (409).

The heme oxygenases (HO) degrade heme by cleaving the porphyrin ring and generating biliverdin and carbon monoxide (CO). Biliverdin is rapidly reduced to bilirubin by biliverdin reductase. The bilirubin-biliverdin system provides a potent antioxidant mechanism for protecting the cell (395). There are two HOs, HO-1 and HO-2. HO-1, the most abundant form, is highly concentrated in the spleen and degrades heme from senescent red blood cells. HO-1 is induced by heme, oxidative stress, and agents that induce heat shock proteins. HO-2 is a noninducible form localized in the brain and testis (395). Both CO and NO function in neuronal transmission of signals to target cells such as the intestine (410), and are involved in endothelial cell-dependent relaxation (411). Interestingly, CO, like NO, is a potent inhibitor of COX. However, NO has a very short half-life and must be produced close to the target, whereas CO is extremely stable and can diffuse over large distances. Hence, the products of HO-2 may interact with mitochondrial energetics through CO and with mitochondrial ROS through the bilirubin-biliverdin antioxidant system.

Acting together, these various enzymes form an integrated metabolic network between the mitochondria and the nucleus-cytosol. This network would appear to be central to maintaining the necessary balance between the two interdependent information storage and retrieval systems.

### 11.1.16 Nature of Inherited mtDNA Variation

Mitochondrial DNA variation falls into two major classes, maternally transmitted variation, which is passed through the female germline, and somatic mtDNA mutations, which accumulate in tissue cells with age due to the continual replication of mtDNA throughout animal life. Maternally transmitted variation can be deleterious and relatively rapidly eliminated by purifying selection, thus causing maternally inherited disease. Neutral or near neutral variants accumulate in human populations by genetic drift and may be beneficial in particular environments and thus enriched by adaptive selection. Deleterious mutations are constantly arising in the population and being removed at the same rate by selection. Hence, all deleterious mutations must have arisen recently. Neutral mutations are constantly arising and are retained or lost by chance. Hence, they can be either recent or ancient. Adaptive (beneficial) mutations are the rarest class, since most functional mutations degrade a gene function rather than enhance it. However, in the case of mtDNA genes that regulate mitochondrial metabolism, functional variants that may be deleterious in one environment can be advantageous in another environment. Thus, adaptive mutations might arise frequently due to the high mtDNA mutation rate, but only become enriched when individuals bearing that mutation are exposed to a new environment such as might result from climatic change or migration. Hence, adaptive mtDNA variants should be ancient, occur at the base of new branches of the mtDNA tree, and correlate with specific geographic domains.

Somatic mtDNA mutations can also be deleterious, neutral, or adaptive, though the majority should be either deleterious or neutral. Since somatic mtDNA mutations would accumulate in post-mitotic cells, the ability of the mitochondria to repair damage would decline as the deleterious mutations accumulate, ultimately resulting in cellular energetic failure and apoptosis. It is now clear that the accumulation of somatic mtDNA mutations is the aging clock for post-mitotic tissues.

### 11.1.17 Three Classes of Inherited mtDNA Variants

Inherited mtDNA variants can be deleterious and cause disease, neutral and accumulate in the population by drift, or beneficial and be enriched by adaptive selection. All three classes have now been discovered in the human mtDNA.

**11.1.17.1 Deleterious mtDNA Mutations.** Of the three classes of inherited mtDNA mutations, the deleterious mutations are the most conspicuous in their impact on the human condition. Deleterious mtDNA mutations fall into two broad classes: rearrangement mutations, including insertions and deletions, and nucleotide

substitution mutations. Most mtDNA rearrangement mutations are relatively large and thus frequently remove one or more of the mtDNA tRNA or rRNA genes. Hence, most mtDNA rearrangement mutations result in partial mitochondrial dysfunction. Since mtDNA deletions are lethal, they are always found in patients in the heteroplasmic state in association with normal mtDNAs and are rarely transmitted through the female germline. Duplications within mtDNA are less deleterious and thus can be maternally transmitted. However, they also have the capacity to undergo internal homologous recombination, resulting in reciprocal deletions that cause progressive, multisystem disease (412).

Base substitution or insertion–deletion mutations affect only one gene. These fall into two classes: mutations that alter 1 of the 13 polypeptide genes, resulting in biochemical defects in specific respiratory complexes (polypeptide mutations) and mutations that alter a tRNA or an rRNA gene, resulting in defects in mitochondrial protein synthesis (protein synthesis mutations) (412). Depending on the severity of the effect of the nucleotide substitution, it either may only survive if heteroplasmic when severe or may be either heteroplasmic or homoplasmic when mild. For polypeptide genes, nucleotide substitutions that change an amino acid are said to be coding or nonsynonymous (NS) mutations, and their frequency in a population for a particular gene sequence is reported as  $K_a$ . The potential phenotype severity of a polypeptide amino acid substitution (missense) mutation can be estimated by the interspecific amino acid conservation index (CI). CI is the ratio of the number of species that have the pre-variant amino acid in the mutant position divided by the total number of species analyzed. Amino acids with high CIs must be functionally important since mutations that arose in these positions must have been repeatedly eliminated by purifying selection.

A large number of deleterious mtDNA rearrangement and base substitution mutations have been identified over the past 24 years since the first diseases resulting from spontaneous rearrangement (7) and inherited nucleotide substitution mutations (4–6) were first reported. The known pathogenic mtDNA mutations are available through the MITOMAP website ([www.mitomap.org](http://www.mitomap.org)) and are discussed in detail later.

**11.1.17.2 Neutral Mutations.** Neutral mutations also fall into two classes: Those that do not alter a gene product and those that do change a gene product but have a minimal effect on the function of the product. Among the mtDNA mutations that alter an mtDNA nucleotide without altering a mitochondrial function, the most common type is the mutations that alter a third codon position and thus do not alter an amino acid. Such mutations are designated silent or synonymous (S), and the frequency of S mutations for a gene within a population is  $K_s$ . Since S mutations are not acted on by selection, they accumulate by chance and thus at a relatively constant rate over time. Thus, the  $K_s$  value provides an estimation of

the time of divergence between two mtDNA sequences. Some mutations in polypeptide genes change an amino acid, but the alteration has little if any deleterious effect on the function of the polypeptide. In polypeptide genes, such mutations generally change amino acids with a low CI.

The level of accumulation of missense mutations along mtDNA lineages is thus a consequence of the time that missense mutations have had to accumulate and the rate at which natural selection removed the mutations. This is calculated by the ratio of  $K_a$  and  $K_s$  ( $K_a:K_s$ ), with  $K_s$  normalizing for the time of divergence.

Since different mtDNA lineages never mix and thus never recombine, base substitution mutations must accumulate as sequential mutations along radiating mtDNA lineages. However, certain neutral mutations might become enriched by selection if they are linked to an advantageous mutation, a process known as “hitchhiking.”

**11.1.17.3 Adaptive Mutations.** Presumably ancient adaptive mutations could occur in any functional element within the mtDNA, including polypeptides, tRNAs, rRNAs, and functional control region (CR) elements. Currently, the most revealing information is available for ancient polypeptide missense mutations. By the process of elimination from deleterious and neutral mutations, adaptive mutations would be expected to change important mitochondrial functions, yet not only have resisted being eliminated by purifying selection but in many cases have been expanded in specific regional human populations. For polypeptide genes, adaptive mutations would change amino acids with a high CI and yet also be ancient and thus found in one of the internal nodes of the mtDNA tree. The adaptive importance of such mutations can be additionally demonstrated by observing that the same mutation appears multiple independent times on different human mtDNA lineages in similar environmental contexts.

### 11.1.18 The mtDNA Tree

Because of the strict maternal inheritance of mtDNA, it is possible to reconstruct the entire mutational history of human mtDNA, which resulted from the sequential accumulation of base substitutions along radiating maternal lineages. As expected, the accumulation of mtDNA mutations results in a progressively branching lineage. What is surprising, however, is that the branches of the mtDNA tree correlate dramatically with the geographic origin of indigenous human populations.

We now understand that the geographic association of specific mtDNA lineages is the product of environmental selection that enriched for specific mtDNA types. This is a direct consequence of the fact that mitochondria generate energy for two purposes: production of ATP to perform work and generation of heat to maintain our body temperature at 37°C. The ratio of ATP production to heat generation is determined by the coupling efficiency of OXPHOS. Sequence variants in mtDNA

that alter the coupling efficiency of OXPHOS can then change the balance from more ATP and less heat in tropical and subtropical Africa to more progressively more heat and less ATP in temperate Eurasia and Arctic Siberia (321,360,361,413).

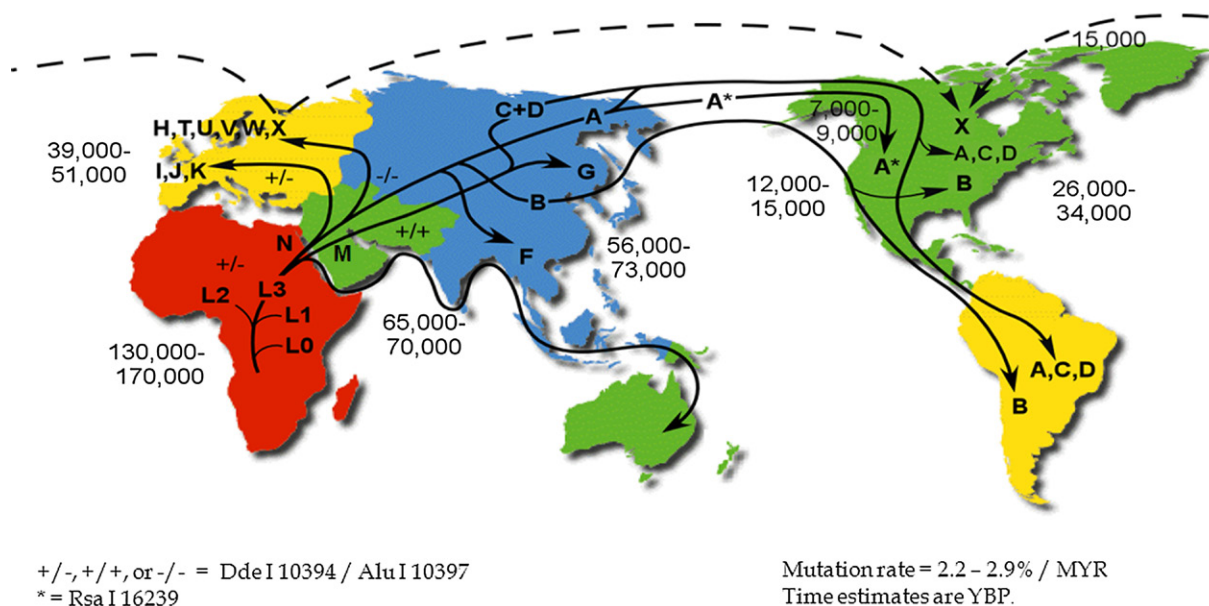

### 11.1.19 Phylogeny of Polymorphic Variation

The unique correlation between mtDNA variation and human geographic origin was first observed when samples from Africans, Asians, and Europeans were analyzed for *HpaI* mtDNA restriction site polymorphisms and the mtDNAs of each population were found to have distinct polymorphisms (414). Further characterization of restriction site polymorphisms revealed that all mtDNA types would fit into a single tree (415), with the greatest mtDNA variation and the root of the tree being in Africa (359,415,416) and with specific branches radiating into the different continents (417). The sequence variation found in a particular mtDNA is designated the mtDNA haplotype, and a group of related haplotypes that form discrete branches of the tree are called “haplogroups.” Haplogroups are defined by ancient sequence polymorphisms that occur at the base of a particular branch of the mtDNA tree (358,360,417).

The most diverse and thus most ancient mtDNAs are found in Africa, with the sequence divergence giving an estimate of African occupation of between 150,000 and 200,000 years before present (YBP). African mtDNAs fall into four major haplogroups: L0 (oldest), L1, L2, and L3 (youngest). L0, L1, and L2 represent about 76% of all sub-Saharan African mtDNAs and are defined by a *HpaI* restriction site at np 3592 (macro-haplogroup L [L0, L1, and L2]) (see Figure 11-5). In northeastern Africa, two mtDNA lineages, M and N, arose from L3 about 65,000 YBP. These were the only mtDNA lineages that succeeded in leaving sub-Saharan Africa and radiating into Eurasia to give all of the Eurasian mtDNAs. In Europe, haplogroup N gave rise to haplogroups H (about 45% of European mtDNAs), T, U, V, W, and X (about 2%) as well as I, J (about 9%), and K (Uk). The European lineages arose about 40,000–50,000 YBP. In Asia, lineages M and N radiated to give rise to a plethora of mtDNA lineages. These include haplogroups A, B, F, and others from N, and haplogroups C, D, G, and others from M (417).

As Asians migrated northeast into Siberia, haplogroups A, C, and D became progressively enriched, such that they became the predominant mtDNA lineages in the indigenous peoples of extreme northeastern Siberia, Chukotka. When the Bering land bridge appeared about 20,000–30,000 YBP, people harboring these mtDNA haplogroups were in a position to migrate into the New World, where they founded the Paleo-Indians. After the land bridge submerged, haplogroup G arose in central Asia and moved into northeastern Siberia to populate the area around the Sea of Okhotsk. About 12,000–15,000 YBP, a migration carrying haplogroup B started from eastern Central Asia

**HUMAN MIGRATIONS: NON-RANDOM DISTRIBUTION OF mtDNA  
VARIATION SUGGESTS SELECTION**  
**Striking Discontinuities:**  
**Tropical Africa to Temperate Eurasia to Arctic Siberia**

**FIGURE 11-5** Diagram outlining the migratory history of the human mtDNA haplogroups. *Homo sapiens* mtDNAs arose in Africa about 130,000–170,000 years before present (YBP), with the first African-specific haplogroup branch being L0, followed by the appearance in Africa of lineages L1, L2, and L3. In northeastern Africa, L3 gave rise to two new lineages M and N. Only M and N mtDNAs successfully left Africa about 65,000 YBP and colonized all of Eurasia and the Americas. The diverse array of mtDNA lineages M and N spawned are clustered together as macrohaplogroups M and N. The founders of macrohaplogroup M moved out of Africa through India and along the Southeast Asian coast down along the Malaysian peninsula and into Australia generating haplogroups Q and M42 around 48,000 YBP. Subsequently, M moved north out of Southeast Asia to produce a diverse array of mtDNA lineages including haplogroups C, D, G and many other M haplogroup lineages. In northeast Asia, haplogroup C gave rise to haplogroup Z. The founders of macrohaplogroup N also moved through Southeast Asia and into Australia generating haplogroup S. In Asia, macrohaplogroup N mtDNAs also moved north to generate central Asian haplogroup A and Siberian haplogroup Y. In western Eurasia, macrohaplogroup N founders also moved north to spawn European haplogroups I, W, and X and in western Eurasia and gave rise to sub-macrohaplogroup R. R moved west to produce the European haplogroups H, J, U, and V and also moved east to generate Australian haplogroup P and eastern Asian haplogroups F and B. By 20,000 YBP, mtDNA haplogroups C and D from M and A from N were enriched in north-eastern Siberia and thus were positioned to migrate across the Bering land bridge (Beringia) to give rise to the first Native American populations, the Paleo-Indians. Haplogroups A, C, and D migrated throughout North America and on through Central America to radiate into South America. Haplogroup X, which is most prevalent in Europe but is also found in Mongolia though not in Siberia, arrived in North America about 15,000 YBP, but remained in northern North America. Haplogroup B, which is not found in Siberia but is prevalent along the coast of Asia arrived in North America about 12,000 to 15,000 YBP and moved through North and Central America and into South America combining with A, C, and D to generate the four dominant Paleo-Indian haplogroups (A-D). A subsequent migration of haplogroup A out of the Chukotka peninsula about 7,000 to 9,000 YBP gave rise to the Na-Déné (Athabaskins, Navajo, Apache, etc.). Subsequent movement across the Bering strait, primarily carrying haplogroups A and D after 6,000 YBP, produced the Eskimo and Aleut populations. Most recently, eastern Asian haplogroup B migrated south along the Asian coast through Micronesia and out into the Pacific to colonize all of the Pacific islands (Reprinted from <http://www.mitomap.org> (1).)

and moved along the coast to the New World, bypassing arctic Siberia. Haplogroup B then mixed with A, C, and D in temperate North and South America and tropical and subtropical Central and South America to generate additional Paleo-Indian groups. About 15,000 YBP, haplogroup X crossed the arctic to the New World in a migration that settled in the Great Lakes region, such that today 25% of the Ojibwa mtDNAs are haplogroup X (417).

Later migrations from northeastern Siberia, carrying a modified lineage of haplogroup A, founded the Na-Déné populations about 9500 YBP. More recently, immigrants from Siberia bearing derived lineages of haplogroups A and D moved along the Arctic Circle and founded the populations of Eskimos and Aleuts (417).

### 11.1.20 Adaptive mtDNA Variants in Human Evolution, Longevity, and Disease

The phylogeographic distribution of mtDNA haplogroups reveals two striking discontinuities in human mtDNA diversity. The first occurs between sub-Saharan Africa and Eurasia. Virtually all of the sub-Saharan African mtDNA diversity remained in Africa, while only derivatives of lineages M and N colonized temperate Eurasia. The second occurs between temperate Central Asia and Arctic Siberia, where the plethora of Asian mtDNA types are markedly reduced to only three ancient mtDNA lineages (A, C, and D). Thus, the major transitions in mtDNA types correlate most strongly with

latitude. This suggests that climatic selection may have enriched for mtDNA variants that changed the coupling efficiency of mtDNA and thus permitted humans to survive in the colder northern climates (321,360,361).

Evidence that climatic adaptation has influenced the geographic distribution of mtDNA diversity was first obtained by analyzing the amino acid replacement (NS) ( $K_a$ ) to silent (S) ( $K_s$ ) mutation ratios ( $K_a:K_s$ ) from the 13 mtDNA open reading frames of mtDNA associated with tropical and subtropical Africa, temperate Europe, and arctic Siberia. This revealed that the amino acid sequence of the *ATP6* gene was highly variable in the arctic, but was strongly conserved in the tropics and temperate zone; *CYTb* was hypervariable in temperate Europe, but conserved in the tropics and arctic; and *COI* was variable in the tropical Africa, but invariant in the temperate and arctic regions. Variation was also observed in multiple ND subunits (360). Such regional gene-specific variation would not be expected if all mtDNA mutations were neutral and thus accumulated purely by chance (genetic drift).

The geographic constraints on mtDNA protein variation were further validated by positioning all of the mtDNA variants from over 1000 complete mtDNA coding sequences collected from around the world. Mutations that were found in a single mtDNA haplotype must be new mutations, while those that were shared by similar mtDNAs must have arisen in a common ancestor. By this logic, all mutations could be arranged into a sequentially mutational tree.

Based on the position of the sequence variant in the tree and the effect that the variant had on the protein function, the mtDNA variants can be divided into three classes: (1) recent mutations many of which alter functionally important amino acids and thus are potentially disease causing, (2) ancient mutations that are either synonymous or alter weakly conserved amino acids and thus are likely to be neutral or near neutral, and (3) ancient mutations that change highly evolutionarily conserved amino acids and must be adaptive. Of the ancient missense mutations, about 74% are weakly conserved with an average CI of  $23.3\% \pm 14.9\%$ , while about 26% alter highly conserved amino acids with a CI of  $85.1\% \pm 9.2\%$ . By comparison, the average interspecific CI of the 22 known pathogenic mtDNA replacement mutations is  $93.3\% \pm 13.3\%$ , which is only slightly higher than that of the conserved ancient variants (361). Thus, the ancient conserved variants are almost as highly conserved as the pathogenic variants. Yet unlike the pathogenic variants, which are eliminated by purifying selection within a few generations, these ancient conserved variants have resisted purifying selection and survived and expanded in the human population over tens of thousands of years. Therefore, they cannot be deleterious. Rather, they must be adaptive and may represent mutations that altered the mtDNA coupling efficiency and permitted people to adapt to different environments (321,360,361).

Confirmation that this interpretation is correct has now come from multiple different observations. First, these

ancient missense mutations frequently initiate geographically constrained branches of the mtDNA tree, meaning that individuals carrying these mutations were able to survive and multiply in new geographic regions. For example, macro-haplogroup N, which left tropical Africa to colonize temperate Eurasia, is founded by two missense mutations, the *ND3* G10398A, which causes an A114T amino acid substitution, plus the *ATP6* G8701A, which causes an A59T substitution. Second, the relative frequency of ancient NS to S mutations (NS:S) increases from south to north, indicating that the change in environment has resulted in an increased rate of fixation of missense mutations. This differential is particularly striking for haplogroups that reside in the arctic and subarctic. The mean internal branch NS:S ratio for northeastern Siberian–North American haplogroups A, C, D, and X was 0.61, much higher than the mean for the nonarctic haplogroups of 0.39, the mean for the African L haplogroups of 0.31, or the mean for the Native American haplogroup B, which bypassed the cold selection of Siberia, of 0.38. Furthermore, the CI of the arctic missense mutations is higher than those of the warmed climates, with the CIs of the arctic variants of haplogroups A, C, D, and X being 51%, that for the remaining global haplogroups being 39%, that of L being 36%, and that of B being 31%. A similar trend is seen for the European branches of the mtDNA tree. The frequency of ancient replacement mutations (NS:S) for haplogroup H is 0.48, J is 0.66, and IWX is 0.63, while that for Africa is 0.31. The NS:S ratio for haplogroup T is only 0.31, but that is because T was founded by a single highly conserved founding replacement mutation in the *ND2* gene (np 4917) with a very high CI of 20.3. Thus, adaptive changes fall into two categories: either the lineage accumulates multiple missense mutations, each changing a reasonably conserved amino acid, or the lineage changes only a few amino acids, but each change alters an amino acid with a high CI.

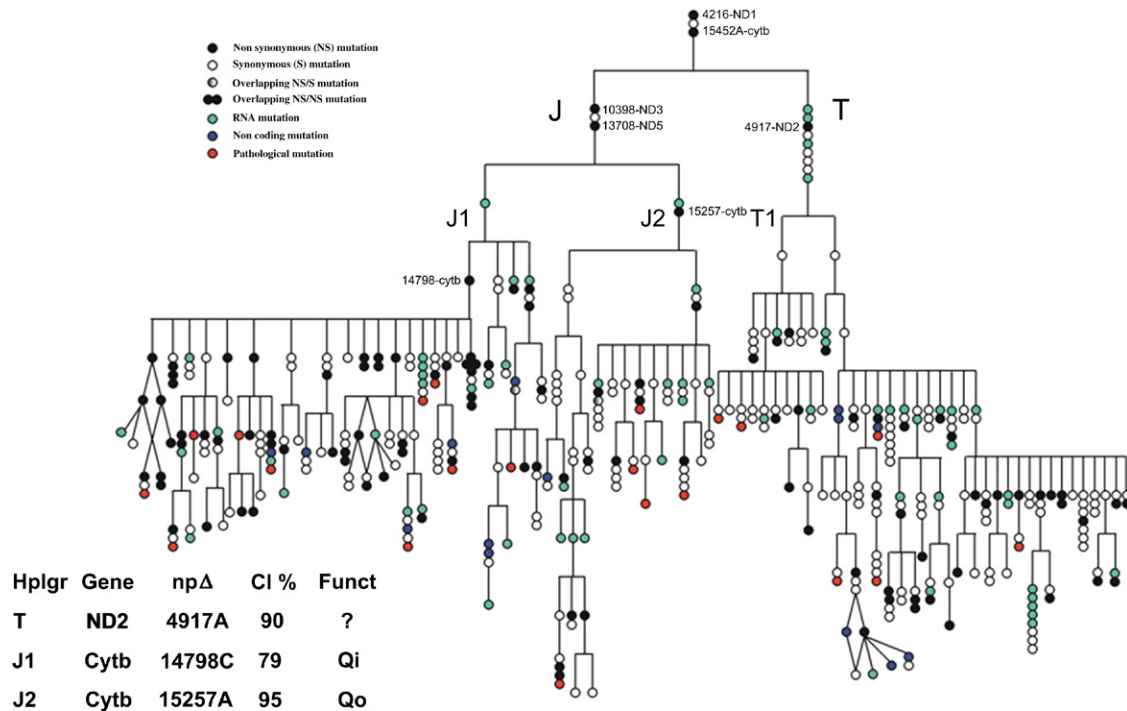

Examples of the adaptive mtDNA mutations that occur in the arctic mtDNAs include two replacement mutations (*ND2* np 4824G [T119A] and *ATP6* np 8794T [H90Y]) for haplogroup A; two replacement variants (*ND4* np 11969A [A404T] and cytochrome *b* np 15204C [I153T]) for haplogroup C; an *ND2* np 5178A (L237M) variant for haplogroup D; and an *ND5* np 13708A (A458T) variant for a sublineage of haplogroup X. This latter variant also appears in European haplogroup J (Figure 11-6).

The European sister haplogroups J and T provide the clearest example of the two classes of adaptive mutation strategies: several less conserved mutations versus a few highly conserved mutations. J and T share a common root involving two amino acid substitutions: *ND1* np 4216C (Y304H) and *CYTb* np 15452A (L236I). J and T then diverge. Haplogroup T is founded by the single nodal adaptive mutation: *ND2* np 4917G (N150D), the most conserved *ND2* polymorphism found (361).

Haplogroup J has two replacement mutations at its root: *ND3* np 10398G (T114A) and *ND5* np 13708A

## BRANCHES OF mtDNA TREE ARE FOUNDED BY VARIANTS IN CONSERVED AMINO ACIDS: EUROPEAN HAPLOGROUPS T & J

**FIGURE 11-6** The European haplogroup J and T branches of the human mtDNA tree shows the nodal mtDNA missense proposed to have been adaptive. The interspecific sequence conservation of the ND2 4917A which defines haplogroup T and the cytb 14798C and 15257A variants that define subhaplogroups J1 and J2 are given in the lower left hand corner of the figure. The sequence variants in ND3 at 10398, ND5 at 13708 and cytb at 14798 have been observed repeatedly in different branches of the human mtDNA tree. Haplogroups J and T have been observed to increase the penetrance of the milder LHON mutations, to be protective of AD and PD and to be enriched in the very old.

(A458T), the second being the same variant found in haplogroup X. Haplogroup J then splits into two subhaplogroups J1 and J2, each defined by a major cytochrome *b* mutation. The J2 variant *CYTB* mutation is at np 15257A (D171N) and the J1 *CYTB* mutation is at np 14798C (F18L). The np 14789C mutation is also found at the root of sub-haplogroup Uk. The np 15,257 and np 14,789 variants alter well-conserved amino acids with CIs of 95% and 79%, respectively. The 15,257 variant alters the outer coenzyme Q binding site ( $Q_o$ ) of complex III, which contacts the Rieske ISP, while the np 14,798 site alters the inner coenzyme Q binding site ( $Q_i$ ) of complex III (361). Since the  $Q_o$  and  $Q_i$  binding sites are essential for complex III proton pumping via the Q cycle, the np 14,798 and 15,257 variants are both likely to have disconnected electron flow through complex III with proton pumping. This would reduce the coupling efficiency of mitochondrial OXPHOS by one-third, thus requiring burning more calories for the same ATP, proportionately increasing heat generation.

That these population variants are clinically relevant has become apparent from studies that correlated mtDNA haplogroups with longevity and degenerative disease. In an Italian study, mtDNA haplogroup J was

found to be overrepresented in centenarians (418,419). Similarly, in an Irish centenarian study, J2 was overrepresented (420), and in a Finnish study of individuals over 90 years, J2, Uk, and WIX were enriched (421). In Japanese centenarians, a sublineage of haplogroup D was enriched (422,423). Hence, specific mtDNA lineages from Europe and Asia are protective against the ravages of aging.

Some of these same mtDNA lineages have also been found to be protective against neurodegenerative diseases. Haplogroups J and Uk are underrepresented in Parkinson disease (PD) (424) and haplogroup T is underrepresented in Alzheimer disease (AD) patients (425,426). The repeated association of haplogroups J1 and Uk with longevity and neuroprotection is particularly illuminating because both haplogroups encompass the same *CYTB* mutation at np 14,798. Such convergent evolution provides strong support for the functional importance of the *CYTB* mutations.

In other studies, haplogroup T has been found to be overrepresented in bipolar affective disorder (427) and haplogroup J has been found to be consistently associated with milder mtDNA missense mutations that are associated with the midlife blindness of LHON (428–431).

Several studies have begun to address the biochemical basis of these associations between mtDNA population polymorphisms and disease. The internal branch mtDNA missense mutations are functionally relevant, which has been demonstrated by comparing the sperm mobility of males harboring the different mtDNA haplogroups. Sperm flagellar motion is driven primarily by ATP generated from the mitochondria in the midpiece. Therefore, sperm with partially uncoupled mitochondria should swim slower than those with coupled mitochondria. As expected, sperm from haplogroup H subjects swam significantly faster than those from T subjects (432), and those of haplogroup U that harbor CYTB missense mutations swim significantly more slowly than those without (433). Moreover, in Europe, individuals who harbor uncoupling CYTB mutations occur in higher frequency in northern Europe than in southern Europe. This is consistent with people who generate on average more heat wishing to live in colder climates (433).

Analysis of somatic cell cybrids harboring mtDNAs from macrohaplogroup L which harbors the ND3 nt 10398 T114A and ATP6 nt 8701 A59T are associated with altered mitochondrial  $\text{Ca}^{++}$  levels and pH (434) and comparison of cybrids harboring haplogroup Uk versus H mtDNAs revealed differences in mtDNA and mtDNA RNA levels, mitochondrial protein synthesis, cytochrome oxidase activity, oxygen consumption, mitochondrial inner membrane potential, and growth capacity (435). Thus, the functional mtDNA variants that founded specific mtDNA lineages affect mitochondrial physiologic functions.

How can the same variants be associated with increased life span and protection against certain diseases on the one hand, yet increase the predilection of developing other degenerative diseases on the other? Additionally, if mtDNA haplogroup variants are deleterious, why do they become enriched in certain populations in apposition of the action of purifying selection? One study has suggested that the reason is that the same variant can be beneficial and thus selectively enriched in one environment but deleterious in another environment. The nt 3394 T>C (Y30H) variant is such a case. This was first observed in association with LHON (430,436–438) and found to reduce complex I activity and cellular respiration between 7% and 28% on the Asian B4c and F1 haplogroup backgrounds. However, complex I activity between B4c and F1 mtDNAs which harbor the common 3394T allele can also differ by 30%. In Asia, the 3394C variant is most commonly associated with the M9 haplogroup which is rare at low elevations but increases in frequency with elevation to an average of 25% of the Tibetan mtDNAs (OR = 23.7). In high altitude Tibetan and Indian populations, the 3394C variant has been observed on three different macrohaplogroup M haplogroup backgrounds, and it is enriched on the M9 background in Tibet and the C4a4 background on the Indian Deccan Plateau (OR = 21.9). When present

on the M9 background, the 3394C variant is associated with a complex I activity that is equal to or higher than that of the 3394T variant on the B4c and F1 backgrounds. Hence, the 3394C variant can either be deleterious or beneficial depending on its haplogroup and environmental context (439).

### 11.1.21 Somatic mtDNA Mutations in Degenerative Diseases, Cancer, and Aging

Since mitochondrially generated ROS would damage mitochondrial macromolecules, including mtDNA, the continual generation of ROS during OXPHOS would be expected to result in the age-related accumulation of somatic mtDNA mutations. As the number of functional mtDNA templates decline with age, the ability of the mitochondria to repair damage to mitochondrial OXPHOS would ultimately decline until the mtPTP is activated and the cells are destroyed by apoptosis. The loss of cells within the tissue would result in organ decline, leading to the age-related accumulation of clinical symptoms, the hallmark of aging. Therefore, it follows that the accumulation of somatic mtDNA mutations may be the aging clock in animals.

Consistent with this hypothesis, both rearrangements and base substitution mutations have been found to accumulate in those mammalian tissues most prone to the effects of aging. Moreover, since most common degenerative diseases also have a delayed onset and progressive course, the accumulation of somatic mtDNA mutations would result in the progressive decline of mitochondrial function, which would push the subclinical phenotype of individuals who had inherited a partial mitochondrial defect across their expression thresholds resulting in disease. Thus, somatic mtDNA mutations may be important in both the onset and the progression of the age-related diseases and mtDNA diseases as well (8–10).

The age-related accumulation of somatic mtDNA mutations in post-mitotic human tissues correlates with the age-related decline in mitochondrial OXPHOS enzymes. OXPHOS enzyme activities have been shown to decline with age in human and primate skeletal muscle (440–442), liver (443), and brain (444). The common 5-kbp (4977-np) deletion has been quantitated in these same tissues (445) and shown to accumulate with age in skeletal muscle (446,447), heart (448–450), extraocular muscle (451), the basal ganglia and cerebral cortex of the brain (452,453), and other tissues (454,455). The highest levels of the common deletion are found in the brain, where deletion levels increase over 10,000-fold from young to old individuals, with maximum levels of the 5-kbp deletion in 80-year-olds exceeding 10% in the basal ganglia and 2–3% in the cortex. By contrast, less than 0.0001% of the 5-kbp deletion accumulates with age in the human cerebellum (452,453,456).

The accumulation of the 5-kbp deletion appears to be but the “tip of the iceberg.” Using long-extension

polymerase chain reaction (PCR) (457) to amplify the entire mtDNA in a single fragment, skeletal muscle mtDNAs from subjects under 40 years of age were found to generate virtually all full-length mtDNA molecules. By contrast, skeletal muscle mtDNAs of subjects older than age 75 years gave very few full-length molecules, but instead gave a wide variety of smaller length PCR products, suggesting extensive mtDNA rearrangement (458). Similar results were obtained in a second less extensive study (459). In an attempt to estimate the amount of rearrangement of mtDNA in skeletal muscle, undigested mtDNA was run on agarose gels and analyzed by Southern blotting and hybridization with a total mtDNA probe. Parallel lanes included chronic progressive external ophthalmoplegia–Kearns–Sayre syndrome (CPEO-KSS) patient DNAs with known levels of the 5-kbp deletion. The Southern blots from younger subjects gave complex patterns, indicating that muscle mtDNA must harbor a wide range of mtDNA conformations including different levels of super-coiled, nicked, and concatenated molecules. In addition, the two CPEO-KSS samples had two extra bands, one migrating slightly faster than the linearized 16.5-kbp mtDNA at 11.5 kbp, consistent with linearized deleted mtDNA; and the other migrating faster than any of the slower migrating super-coiled, nicked, and concatenated molecule bands and probably representing super-coiled or nicked deleted mtDNA. The muscle mtDNAs of the old subjects had all of the same bands as the younger subjects, but in addition all of these samples had an additional diffuse band in the same region as the patient's super-coiled or nicked rearranged mtDNA. This suggests that elderly individuals may accumulate a significant level of heterogeneously rearranged mtDNA molecules (458). This same phenomenon has been observed in the mouse, where long-extension PCR revealed increased mtDNA rearrangements in hearts of old mice but not in those of young mice. Southern blots of undigested mtDNA revealed the accumulation of a novel mtDNA band that is present in old but not young animals. Moreover, this band is absent in calorie-restricted animals (460). Similar age-related accumulation of mtDNA rearrangements has been documented in chimp heart (461).

A more general survey of mtDNA base substitutions in brain using denaturing gradient gel electrophoresis, cloning, and sequencing revealed a spectrum of point mutations, and single base insertions and deletions in the D-loop, with 35–41% of the molecules differing in at least one position. Heteroplasmic mutants were much less common in coding regions. Point mutations were observed to increase 2.5-fold and insertion–deletions 7.7-fold between ages 28 and 96–99 years. Two distinctive CR base substitution mutations were T146C and T195C (477) (462). Using a similar technique to analyze the mtDNAs from diploid fibroblasts cultured from individuals of various ages also revealed distinctive CR variants, including T146C, T152C, T195C, A249G, T285C,

A368G, 383i, and T414G. The most prevalent variant was T414G located at the *Tfam* binding site adjacent to LSP. This variant was found in 50% of the fibroblast cultures derived from patients over 65, but not seen in the cultures of younger individuals. In some individuals, the percentage of mutant mtDNAs exceeded 50% (463). In studies of skeletal muscle, a T408A promoter mutation and a A189G O<sub>H</sub> mutation were found to accumulate with age (464); and a T150C O<sub>H</sub> mutation was found to accumulate with age in white blood cells (465). These mtDNA CR mutations appear to be highly tissue specific. The T414G mutation can be detected at low levels in skeletal muscle by using a highly specific and sensitive protein nucleic acid (PNA)-clamping PCR method. However, this same method has been unable to detect the T414G mutation in the brains of even very elderly people (466).

Analysis of the distribution of somatic mtDNA mutations in aging skeletal muscle indicates that individual mutations are regionally localized and thus may be clonally amplified, just as CPEO-KSS rearrangement mutations are differentially distributed along muscle fibers. Histologic analysis of muscle tissues from old subjects has revealed periodic COX-positive and COX-negative regions (467,468). Each COX-negative region was found through *in situ* hybridization either to contain a specific mtDNA deletion clone or to be deficient in mtDNA (451). Similar analysis of individual cardiomyocytes from human hearts has indicated that individual cells have high levels of specific mtDNA rearrangements, while other cells have only normal mtDNA (469). Furthermore, analysis of intestinal crypt cells has revealed that spontaneous somatic mtDNA mutations arise in the *COI* genes in the stem cells at the base of the intestinal crypt with age. These segregate to homoplasmic mutants, resulting in the intestine becoming a mosaic of COX-negative and COX-positive crypts as the individual ages (470). This implies that individual somatic mtDNA mutations arise spontaneously and randomly in cells, but once they occur, they are selectively replicated in that all result in respiratory deficiency. This replication phase would be exponential and might explain why the frequency of specific mtDNA deletions appears to increase exponentially with time (447–449,452).

The origin of the high rate of mtDNA mutations is unknown. However, one likely source of new mutations is the generation and subsequent resolution of DNA oxidation products, including thymine glycols and 8-hydroxy-2-deoxyguanosine (8-OHdG) (452,453,456,471). 8-OHdG is the most common form of oxidative DNA damage, though it may not be the main mtDNA mutagen, since mtDNA base substitutions show a 20-fold bias toward transitions over transversions (472), while 8-OHdG is thought to increase the transversion rate (473–475). mtDNA oxidation products might also cause replication errors, increasing the rate of mtDNA rearrangement mutations.

mtDNA seems to be particularly prone to oxygen radical damage. The mitochondrial respiratory chain is the major source of ROS generation, and mtDNA is attached to the mitochondrial inner membrane in close proximity to the OXPHOS complexes (476). This preferential mtDNA oxidative damage has been confirmed in several studies. In young rats, the mtDNA has been reported to contain ~16-fold more 8-OHdG than the nDNA, and this increases another 3-fold in older rats (477,478). Current estimates place the differential 8-OHdG levels of the mtDNA at 10-fold above the nDNA (476). Similarly, mtDNA 8-OHdG levels in human brain were 10-fold higher than nDNA levels and increased with age (479). Levels of 8-OHdG have been reported to increase with age in the mtDNAs of human diaphragm, heart muscle (450,480), and brain (481), and 8-OHdG and the 7.4-kbp deletion to increase with age by the same exponential kinetics in human hearts (450,482).

The preferential accumulation of oxidation damage in mtDNA might imply that mtDNA is deficient in DNA repair. While mtDNA cannot repair thymine dimers (483), the mitochondria do contain uracil DNA glycosylase (484), AP endonuclease (485), and enzymes to repair pyrimidine glycols (486). A variety of other repair activities have been detected by treating cultured cells with DNA-damaging agents, purifying genomic DNA, digesting with endonucleases specific for each type of damage, and using Southern blots of alkaline agarose gels to monitor the removal of the endonuclease sensitive sites from post-treatment cells. By this procedure, it has been found that the mitochondria cannot repair pyrimidine dimers, but they can repair 8-OHdG and adducts for 4NQO and monofunctional alkylating agents. The mitochondria cannot repair *cis*-platinum intrastrand cross-links, consistent with an absence of thymidine dimer repair, but can repair *cis*-platinum interstrand cross-links, suggesting recombinational repair (487–493). It is surprising that the mitochondria would retain active repair systems, yet experience such a high degree of preferential damage. Presumably, the level of repair is set to be sufficient to keep the mtDNAs intact until after reproductive age, at which point sustaining the parents is no longer necessary.

Somatic mtDNA mutations have been proven to be important in longevity by regulating the mtDNA mutation rate. The mitochondrial production of hydrogen peroxide, the central mitochondrial ROS molecule, was countered by targeting the peroxisomal enzyme catalase to the mitochondrial matrix. This resulted in the extension of the mean and maximum life span of the mouse in association with reduced damage to mtDNA and increased mitochondrial resistance to exogenous ROS damage (494). Therefore, the lifelong accumulation of oxidative damage to the mitochondria and mtDNA is important in determining the rate of aging, a result consistent with the “free radical theory of aging” (495).

In two independent studies in which the mouse nDNA-encoded mtDNA polymerase  $\gamma$  (POLG) gene was

replaced by a mutant gene copy in which the 3'-to-5' proofreading exonuclease was inactivated by introduction of a D257A substitution. In both sets of POLG-mutator mice, the steady-state mtDNA mutation level was increased severalfold and the animals exhibited an array of progeric phenotypes, including shortened life span, weight loss, reduction of subcutaneous fat, hair loss (alopecia), curvature of the spine (kyphosis), osteoporosis, anemia, reduced fertility, and heart enlargement. These mice also showed an age-related decline in mitochondrial OXPHOS enzymes, respiration rate, and energy production (496,497). This confirms that aging is the product of mitochondrial decline, which in these cases was caused by the destruction of mtDNA, and the mitochondrial biosynthetic capacity. Both studies also found that POLG-mutator mice did not have increased mitochondrial ROS production. This places mtDNA damage downstream of the mitochondrial ROS production in the normal aging process.

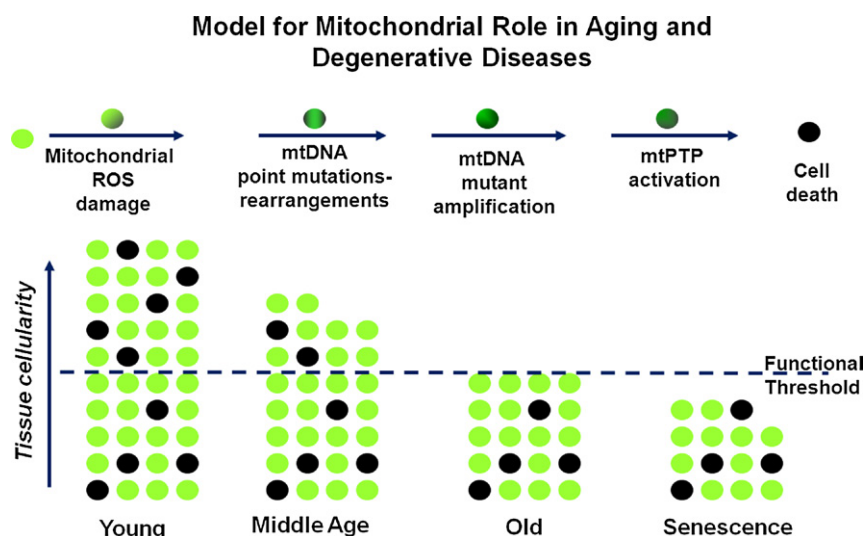

From these observations, we can now refine the pathway involved in the mitochondrial etiology of aging (Figure 11-7). During normal energy production, OXPHOS also generates ROS. This endogenous ROS damages the mitochondrial OXPHOS enzymes, requiring their repair by expression of the genes in the mtDNA. However, in normal animals, ROS also mutagenizes the mtDNA. Ultimately, the percentage of mutant mtDNAs in a cell increases to the point that the remaining mtDNAs are unable to adequately repair the damaged OXPHOS enzymes. At this point, the mitochondrial membrane potential and energy production decline to the point that the mtPTP is activated and the ailing cell is destroyed by apoptosis. Since this progression is the result of random mtDNA mutations, different cells undergo apoptosis at different times. Hence, at any one time only a small fraction of the cells in a tissue are actively undergoing apoptosis (1).

Thus, all of the current evidence supports the hypothesis that the accumulation of mtDNA mutations is the aging clock and that, in most situations, it is the rate of accumulation of oxidative damage that determines the clock rate. Therefore, the longevity of a species will be modulated by the rate of mitochondrial ROS production, the effectiveness of the mitochondrial antioxidant defense systems, the rate of mtDNA mutation, and the effectiveness of mtDNA repair.

## 11.1.22 Inherited mtDNA Diseases

**11.1.22.1 Diseases Resulting from Intragenic Polypeptide Mutations.** Diseases that are caused by mtDNA mutations within a single polypeptide gene are enzyme specific. Consequently, they generally present with more stereotypic clinical phenotypes. Confirmed mtDNA mutations are listed in Tables 11-1–11-3 Panel A, while Panel B refers to reported mtDNA mutations. Confirmed mutations are variants which have been

**FIGURE 11-7** Mitochondrial and cellular model of aging. The upper line of cells shows the mitochondrial role in the energetic life and death of a cell. All post-mitotic cells have a finite probability of dying due to the accumulation of mitochondrial and mtDNA damage associated with OXPHOS ROS production, followed by mutant mtDNA amplification, activation of the mtPTP, and death by apoptosis. The bottom diagram represents the loss of cells in a tissue over the life of an individual through mitochondrial mediated death, black cells. Each individual is born with sufficient extra cells such that even as cells are lost by mitochondrial induced apoptosis, sufficient cells remain to maintain tissue function. Ultimately, however, enough cells are lost that the organ begins to malfunction resulting in the clinical manifestations of old age. The minimum number of cells for the tissue to function normally is indicated by the dashed line (1).

identified in two different laboratories or reports of unrelated families. Additional publications supporting these pathogenic mutations, as well as over 230 other potentially pathogenic mtDNA variants can be found at <http://www.mitomap.org/>.

The first maternally inherited mtDNA polypeptide mutation disease discovered was LHON (4). LHON is generally associated with missense mutations in one of the mtDNA complex I polypeptides (Table 11-1).

#### 11.1.22.2 Leber Hereditary Optic Neuropathy.

LHON is a form of acute or subacute, bilateral, midlife-onset central vision loss associated with the degeneration of the retinal ganglion cell (RGC) layer and optic nerve, resulting in central scotoma. The age of onset is generally in the 20s and 30s, though onset of symptoms can occur from childhood to late adulthood. Typically, the onset and progression of blindness is relatively rapid, with both eyes developing vision loss within a year. The disease is frequently familial, and in all familial cases the affected individuals are related through the maternal lineage. There is a predilection for males to be affected, with the ratio of affected males to females reaching 4:1 in some instances (498–502). While most mtDNA LHON pedigrees manifest primarily LHON, the more severe mutations can exhibit other neurodegenerative disease symptoms. A typical pedigree showing the maternal inheritance of LHON is presented in Figure 11-8

Since the discovery of the MTND4\*LHON11778A mutation in 1988 (4), LHON has been associated with 30 missense mutations. Of these, 15 have been observed in more than one patient or family. Hence, these 15 mutations can be considered to be pathogenic causes of

LHON. These LHON mutations are all complex I gene missense mutations and include MTND1\*LHON 3635A, MTND1\*LHON 3700A, MTND1\*LHON3733A, MTND1\*LHON4171A, MTND4L\*LHON 10663C, MTND6\*LDYT14459A, MTND6\*LHON14482A and 14482G, MTND6\*LHON 14495G, MTND6\*LHON 14502C, and MTND6\*LHON 14568T (see Table 11-1). The remaining 20 sequence variants that have been associated with LHON are considered preliminary since they have only been seen one time, co-occurred with another “pathogenic” mutation, and/or were only found as a homoplasmic variant (see [www.mitomap.org](http://www.mitomap.org) for more information).

Of the top 14 LHON mutations, 3 account for over 95% of cases in Europe (see Table 11-1). These are MTND4\*LHON11778A (69% in European but 95% in Asia) (503), MTND1\*LHON3460A (13%), and MTND6\*LHON14484C (14%). The remaining 11 confirmed mutations are much more rare.

In addition, some of these pathogenic mutations considered as mild pathogenic LHON mutations, including MTND4\*LHON11778A, MTND6\*LHON14484C, and MTND3\*LHON10663C, are commonly associated with the European haplogroup J. This association can now be understood as the result of an interaction between the mild energetic defects associated with the adaptive mutations of this temperate zone haplogroup and the added energetic defect imparted by the recent LHON mutation (428,430,431).

**11.1.22.3 LHON as the Primary Clinical Manifestation.** The three common pathogenic LHON mutations—MTND4\*LHON11778A (4), MTND1\*LHON3460A

More Publications supporting these pathogenic mutations, as well as over 50 other possibly pathogenic variants in LHON patients, can be found at <http://www.mitomap.org/MITOL>. Penetrance values are rough estimates.

Low, anecdotal low degree of vision recovery; Yes, anecdotal moderate to high degree of vision recovery; UN, unknown; NA, not applicable.

<sup>a</sup>The first three mutations listed (in boldface and shaded in gray) represent ~95% of all cases. The remaining mutations are listed in nucleotide order.

<sup>b</sup>H, high amino acid conservation; M, moderate amino acid conservation; L, low amino acid conservation; NA, not applicable; Ter, termination codon.

<sup>c</sup>Het., heteroplasmy: +, detected; -, not detected.

**LEBER HEREDITARY OPTIC NEUROPATHY**  
**African-American LHON Pedigree**  
**ND4 np 11778 G>A arginine 340 to histidine**

Shaded symbols indicate affected individuals. Asterisks indicate individuals examined.

**FIGURE 11-8** Maternally inherited pedigree of LHON due to the MTND4\*LHON11778A mutation. Affected individuals (filled symbols) experience acute onset optic atrophy and central vision loss, generally as young adults. Even though the mutation is essentially homoplasmic, penetrance among maternal relatives is highly variable. Moreover, males are about three to four times more likely to lose their vision than females (4,512).

(504–506), and MTND6\*LHON14484C (507,508)—generally present as LHON with few other clinical phenotypes (see Table 11-1). These mutations represent strong risk factors for developing LHON, have been observed in multiple unrelated LHON families, rarely co-occur with each other, and have not been detected in a large number of control mtDNAs (430,509–511) (see Table 11-1).

**MTND4\*LHON11778A.** The MTND4\*LHON 11778A mutation converts the highly conserved ND4 codon 340 from an arginine to a histidine (4). This mutation typically displays variable expression in families, with males being predominantly affected, and is heteroplasmic in about 14% of cases (512). The MTND4\*LHON11778A mutation also has a highly variable penetrance. Among MTND4\*LHON11778A families, about 33–60% of maternal relatives are affected, with 82% of the affected individuals being male and 18% female (313,512). Furthermore, only about 4% of affected individuals experience visual recovery.

Of the affected individuals, the mean age of onset is 27.6 years, with a range of onset from 8 to 60 years. About 58% of patients show additional ophthalmologic features, including peripapillary telangiectasias, microangiopathy, disc pseudoedema, and vascular tortuosity. Fifty-five percent of patients have a simultaneous onset of

vision loss in both eyes, while the overall mean interocular interval is 1.8 months, and the maximum interval is about 9 months. Once vision loss begins, it can progress rapidly or slowly. The mean length of progression for the MTND4\*LHON11778A mutation is 3.7 months, with a range of 0–24 months. In about 98% of cases, the final visual acuity is 20/200 or worse, while only 2% are better than 20/200 (512). Most cases are limited to optic atrophy, although a variety of other mild abnormalities have been associated with this mutation. These include cardiac conduction defects such as abnormal Q–T interval (513), skeletal abnormalities, and other neurologic signs (500).

In one patient, the MTND4\*LHON11778A mutation has been associated with Wolfram syndrome. In addition to optic atrophy, this patient had diabetes mellitus and sensorineural deafness (514).

Some biochemical studies on the MTND4\*LHON 11778A mutation have reported complex I enzymatic defects ranging from 0% to 50%. However, most studies have found no statistically significant reduction in complex I activity (515–520). By contrast, most studies have observed a reduction in mitochondrial respiration using complex I-linked substrates of 30–50%, while respiration rates using succinate are normal (515,518,519,521). When the MTND4\*LHON11778A mtDNAs are transferred to a different nuclear background by cybrid

transfer, the respiration defect is transferred, indicating that the respiration defect is linked to the mtDNA mutation (515,522,523). The MTND4\*LHON11778A mutation has also been reported to have an increased resistance to rotenone, a complex I inhibitor that acts as a ubiquinone antagonist. The mutant enzyme also has an altered affinity for ubiquinone analogs, though other groups have not detected this alteration in rotenone sensitivity (516,517,521). These observations have led to the postulation that the MTND4\*LHON11778A mutation alters the complex I interaction with ubiquinone. Alternatively, the amino acid change has been hypothesized to compromise the enzyme's energy-conserving (proton translocation) function, or to destabilize ubisemiquinone intermediates, promoting the production of ROS. The absence of an enzymologic defect in the presence of a clear respiration defect might be due to a defect in proton translocation or to an alternation of coenzyme Q affinity that is masked in the enzyme assays by the use of coenzyme Q analog at nonphysiologic concentrations as electron acceptor.

**MTND1\*LHON3460A.** The MTND1\*LHON3460A mutation changes a moderately conserved alanine at codon 52 in the *ND1* gene to a threonine and has been observed to be heteroplasmic in a number of families (504–506). Generally, the clinical manifestations of this mutation are confined to LHON, and only occasionally is the MTND1\*LHON3460A mutation associated with other neurologic signs, though patients harboring this mutation can manifest multiple sclerosis (524,525). Virtually every MTND1\*LHON3460A family is due to an independent mutation (430), and a small percentage of the families are heteroplasmic (313). The number of affected maternal relatives has varied widely in different studies, but can approach 75% (526,527), with between 40% and 80% of all affected individuals being male. Approximately 22% of affected individuals with MTND1\*LHON3460A have been reported to experience visual recovery (528).

The MTND1\*LHON3460A mutation is associated with markedly reduced complex I activity, and a reduction in respiration. In multiple studies of patient cells, the MTND1\*LHON3460A mutation has been found to be associated with a 60–80% reduction in the complex I specific activity (504,515,516,519,520). Despite the pronounced reduction in complex I activity, ATP synthesis in MTND1\*LHON3460A mitochondria is not compromised (529). Respiration studies have shown a roughly 30% reduction in maximal respiration rates using complex I-linked substrates (515,521). In cybrid transfer experiments, the complex I defect transfers faithfully (515), although nuclear genetic backgrounds may alter the magnitude of the functional defect found in cybrids (530). When complex I activity has been titrated with ubiquinone analogs/derivatives, a substrate inhibition pattern was observed (530). This suggests that the primary biochemical defect is in altered ubiquinone binding

affinity, which would be in line with the proposal that both the ND1 and ND6 polypeptides are components of the ubiquinone binding site.

**MTND6\*LHON14484C.** Finally, the MTND6\*LHON14484C mutation changes the weakly conserved methionine at codon 64 in the ND6 protein to a valine. This mutation is generally homoplasmic in LHON families (507,508), having been reported to be heteroplasmic in only a few pedigrees (531).

Clinically, the penetrance of the MTND6\*LHON14484C mutation is comparable to that of the other primary LHON mutations, resulting in symptoms in 27–80% of maternal relatives. Also, the male:female ratio of affected individuals is similarly high compared to that for the MTND4\*LHON11778A and MTND1\*LHON3460A mutations (502,526,528). Most MTND6\*LHON14484C families are likely to be independent mutations, but the MTND6\*LHON14484C mutation is only rarely heteroplasmic (531), suggesting that the mutation is sufficiently mild that most of the mtDNAs must be mutant before a phenotype is likely. This is supported by the strong association of the MTND6\*LHON14484C mutation with haplogroup J, indicating that it is less capable of causing LHON alone than are the MTND4\*LHON11778A and MTND1\*LHON3460A mutations (429,431). Occasionally, the MTND6\*LHON14484C mutation has also been found to co-occur with the MTND4\*LHON11778A mutation (502).

The MTND6\*LHON14484C mutation is additionally noteworthy for the tendency of patients to experience visual recovery. Fully 37–50% of patients with this mutation report visual improvement (see Table 11-1) (502,528). Thus, the MTND6\*LHON14484C mutation has the lowest pathogenicity of the primary LHON mutations and frequently requires additional mtDNA variants to augment its biochemical defect sufficiently to cause disease symptoms.

The biochemical defect of the MTND6\*LHON14484C mutation has proven very difficult to detect. Thus the functional defects associated with this mutation may match the milder genetic and clinical signature of this mutation. In enzyme and respiration analyses on patient lymphoblasts and cybrids, the specific activity of complex I was essentially normal, though maximal respiration rates were reduced 15–20% with complex I-linked substrates (515). Similarly, in independent studies, no reduction in complex I activity was found in MTND6\*LHON14484C-positive patient fibroblasts (532,533), although a third study reported a severe (65%) reduction in complex I activity and an associated 20% reduction in complex I-linked ATP synthesis in their patients (534). One study of platelet mitochondria implicated this mutation in complex I–ubiquinone interactions, since the mitochondria had increased sensitivity to the complex I product inhibitors myxothiazol and NBQH2 (532). While additional studies will be

needed to reach a consensus concerning the functional defects of this mutation, it is apparent that the biochemical defect of the MTND6\**LHON*14484C mutation is milder than that of the MTND1\**LHON*3460A and MTND4\**LHON*11778A mutations.

*Additional Potential LHON Mutations.* Of the 50 rare or provisional LHON mutations, all but three alter mtDNA complex I polypeptides. A complete list is available on Mitomap (<http://www.mitomap.org>).

Two of the rare complex I mutants nicely confirm the pathogenicity of the MTND6\**LHON*14484C mutation. These are the MTND6\**LHON*14482G and A mutations, which alter the same codon as the MTND6\**LHON*14484C mutation but convert the methionine at codon 64 to an isoleucine instead of a valine (535).

The remaining 12 rare LHON mutations have been confirmed as pathogenic (MTND1\**LHON* 3635A, MTND1\**LHON* 3700A, MTND1\**LHON*3733A, MTND1\**LHON*4171A, MTND4L\**LHON* 10663C, MTND6\**LDYT*14459A, MTND6\**LHON*14482A and 14482G, MTND6\**LHON* 14495G, MTND6\**LHON* 14502C, and MTND6\**LHON* 14568T). All of these mutants change moderately to highly conserved amino acids, supporting their pathogenicity (see Table 11-1). Despite their relative low frequency, these mutations should now be routinely assayed in all LHON patients lacking the three most common mtDNA mutations (536).

Of the rare LHON mutations, the most frequent and most severe is the MTND6\**LDYT*14459A mutation (537,538). This mutant has been observed in multiple LHON and dystonia pedigrees. It changes a highly conserved amino acid, results in a severe complex I defect, is frequently heteroplasmic in LHON patients, causes dystonia when homoplasmic, and causes LHON regardless of the mtDNA background haplogroup (539).

At the other extreme is the MTND4L\**LHON*10663C mutation which changes a poorly conserved valine to an alanine at amino acid 65 in the ND4L polypeptide (540). This mutation has been found in three independent LHON patients and was not detected in a large number of ethnic groups or haplotype-matched controls, specifically being absent from 254 controls: 51 J and 203 non-J. All of the MTND4L\**LHON*10663C-positive patients also had haplogroup J mtDNAs. Hence, the MTND4L\**LHON*10663C mutation must also require haplogroup J background to cause a clinical phenotype (428,430).

*The Haplogroup J Connection with LHON.* Early studies of LHON patients revealed a number of variants that were commonly associated with LHON, but were also found at low frequencies in the general population (540,541). The most common variant of these is the MTCYB\**LHON*15257A that changes an amino acid with a CI of 95% (540). Subsequent studies of population mtDNA haplogroups revealed that this and other striking mtDNA variants were all associated with regional

haplogroups; in the case of the MTCYB\**LHON*15257A variant, the association is with the haplogroup J, sub-haplogroup J2 (see Figure 11-6).

Moreover, all of the milder pathogenic LHON mutations showed a predilection for haplogroup J. For example, the MTND4\**LHON*11778A mutation causes a moderate complex I respiration defect, and, of 58 LHON patients harboring this mutation, 29% ( $n=17$ ) were also haplogroup J. For the even milder MTND6\**LHON*14484C complex I defect, of 38 LHON patients with this mutation, 79% ( $n=30$ ) were haplogroup J. Finally, for the very mild MTND4L\**LHON*10663C mutation, 100% of the patients (3 of 3) were also haplogroup J (428,429). Thus these data strongly indicate that haplogroup J, which harbors ancient sequence variants that were adaptive for certain temperate zone conditions, can today exacerbate the biochemical defects of the milder causal LHON variants sufficiently to convert them into pathogenic mutations (360,361,413). Because many of the functional variants of these haplogroups are linked together, it is currently unclear which of the various polymorphisms has the greatest impact on the penetrance of the mild causal mutations.

The root of the haplogroup sister J-T lineage involves two missense mutations: MTND1\*4216C (T304H) and MTCYB\*15452A (L236I) (511,540,542) (see Figure 11-6). The T lineage splits off founded by the highly conserved complex I mutation MTND2\*4917A (D150N), with a CI of 90% (430), and the J lineage is separated by complex I missense mutations MTND3\*10398G (T114A) and MTND5\*13708A (A458T) (540,542). At this point haplogroup J subdivides into sub-haplogroup J1, associated with MTCYB\*14798C with a CI of 79%, a sub-branch of which harbors the MTND1\**LHON*3394C variant common to French Canadian MTND6\**LHON*14484C patients; and sub-haplogroup J2, associated with MTCYB\*15257A (D171N) with a CI of 95% (361,428). At the present time, it is unclear which of these variants contributes to the increased penetrance of the milder LHON mutations.

Other lineage-specific mtDNA variants have also been associated with LHON, though the functional significance of these is even less well established. The MTND1\**LHON*4160C mutation was found together with the MTND6\**LHON*14484C mutation in the mtDNA of a large pedigree with acute-onset optic atrophy as well as other neurologic symptoms. Hence, this mutation may augment the pathogenicity of the MTND6\**LHON*14484C mutation. Support for this hypothesis is that an additional variant MTND1\**LHON* 4136G (Y277C) was found in the same pedigree, but appeared to ameliorate the severity of the symptoms of the combined MTND6\**LHON*14484C and MTND1\**LHON*4160C mutations (543).

The MTCO1\**LHON*7444A variant is novel in that it changes the termination codon of the COI polypeptide, extending the polypeptide by three charged

amino acids (544). This variant has been found in association with the MTND6\*LHON14484C and the MTND1\*LHON3460A mutations (430).

The homoplasmic MTCO3\*LHON9438A variant changes a highly conserved glycine to a serine and has been observed in 2.5% of European patients (545), but also at a low frequency in African and African American controls (546). This variant has also been reported in association with the MTND4\*LHON11778A mutation (547).

*Possible Pathophysiologic Mechanisms of LHON.* The pathophysiologic mechanism by which the LHON mutations cause acute-onset vision loss in young adults remains a mystery. One respiratory defect that ties many of the LHON mutations together is an inhibition in the transfer of electrons from complex I to CoQ<sub>10</sub>. A faulty interaction between CoQ<sub>10</sub> and complex I has been suggested for the MTND6\*LHON14484C mutation (532), implying that the region of ND6 around codons 64 through 72 may be involved in CoQ<sub>10</sub> interaction with complex I. Furthermore, eight other confirmed or putative LHON mutations occur in this region of the ND6 gene, which encompasses an evolutionarily conserved transmembrane helix (helix c) that is similar to the ubiquinone-reacting domain of cytochrome *b* in complex III (532). These are the MTND6\*LDYT 14596A (I26M) (548), the MTND6\*LHON14568T (G36S) (549,550), the MTND6\*- LHON14498T (Y59C) (550), the MTND6\*LHON14482G/A (M64I) (551,552), the MTND6\*LDYT14459A (A72V) (537), the MTND6\*LHON14325C (N117D) (553), the MTND6\*LDYT14495G (L60S) (554), and the MTND6\*LHON 14729A (S132L) (555) mutations. Moreover, the biochemical defects of the MTND6\*LDYT14459A and MTND1\*LHON3460A mutations are similar, suggesting a common mechanism, and ND1 is also thought to be important in electron transfer to CoQ<sub>10</sub>. Finally, the MTND4\*LHON11778A mutation has been suggested to alter rotenone binding and thus CoQ<sub>10</sub> binding (516,517,521). Thus, all of the primary LHON mutations have been implicated in problems with CoQ<sub>10</sub> interaction with complex I. Such a defect might be difficult to accurately evaluate given the difficulties with assaying complex I with the physiologic substrate CoQ<sub>10</sub>, necessitating the use of the CoQ<sub>10</sub> analogs such as decyl-ubiquinone. The possibility that all of these mutations impair electron transfer to CoQ<sub>10</sub> is supported by the observation that all of the primary LHON and LHON associated with dystonia (LDYT) mutations that have been studied (MTND6\*LDYT14459A, MTND4\*LHON11778A, MTND1\*LHON3460A, and MTND6\*LHON14484C) show at least a partial defect in complex I-linked respiration, with reductions in maximal respiration rates for the various mutations ranging from 15% to 40% (556). It is possible that even the small reduction in respiration observed for the MTND6\*LHON14484C mutation might reflect a

significant defect in electron transfer within the mitochondria under physiologic conditions.

Assuming that the primary defect of most LHON mutations is the inhibition of the ETC between complex I and CoQ<sub>10</sub>, then the pathophysiologic basis of the disease might involve chronically reduced energy production and/or increased ROS generation. Mitochondrial ATP production was been found to be strikingly reduced in osteosarcoma 143B cybrids harboring the MTND4\*LHON11778A, MTND1\*LHON3460A, and MTND6\*LHON14484C mutations when the cells were switched from glucose to galactose. Cellular ATP concentrations were reduced to 43%, 36%, and 23%, respectively, relative to the glucose control in 3 h and to 15% or less by 16 h (557).

Increased mitochondrial ROS production has also been demonstrated in Ntera2/D1 cell cybrids harboring the MTND4\*LHON11778A and MTND1\*LHON3460A mutations, but only after the cybrids were induced to differentiate into neurons. This ROS production was likely mitochondrial since its production was inhibited by rotenone. Neuronal differentiation also caused a three-fold reduction in the mtDNA:nDNA ratio, suggesting that mitochondrial function and thus energy production might be further reduced in neurons, thus unmasking a latent mitochondrial defect. Consistent with this interpretation, neuronal differentiation was associated with a 30% reduction in cell number of the LHON cybrids relative to control (558). Further confirmation that the LHON mutations are associated with increased ROS production comes from the observation that lymphoblastoid cell lines harboring the MTND4\*LHON11778A mutation have shorter telomeres than controls, and telomere length is affected by oxidative damage (559).

The LHON mutations are also associated with an increased predilection of cybrid cell lines to undergo apoptosis when grown on galactose. The galactose-induced apoptosis is associated with the mitochondrial release of cytochrome *c*, apoptosis initiating factor, and endonuclease G, and the cytosol from galactose-grown LHON cybrids can induce nDNA fragmentation when added to isolated nuclei (557,560,561). Finally, osteosarcoma 143B cybrids harboring the MTND4\*LHON11778A and MTND1\*LHON3460A mutations were found to be more sensitive to anti-FAS induced cell death, and this was associated with the activation of caspase 3, DNA fragmentation, and increased annexin V staining (562).

While these results confirm that the common LHON mutations cause mitochondrial energetic defects, increased mitochondrial ROS production, and increased apoptosis, they still do not provide a clear indication of why the retinal vessels show telangiectasias and distortion in the preclinical phase or why the RGCs cells are preferentially lost in the acute phase of the disease. The tortuous vessels could be the product of ROS-induced activation of the *HIF1a*-vascular endothelial growth factor pathway, or, alternatively, the mitochondrial

ROS could inactivate the NO vasodilator generated by the vascular endothelial cells, resulting in vasoconstriction and transient ischemia. Similarly, the RGCs might be acutely sensitive to energy deficiency or ROS-induced apoptosis.

It will be necessary to generate a mouse model to resolve these questions. An initial effort to generate a mouse model of LHON that supports the ROS toxicity hypothesis was generated by transducing the retina and RGCs with an adeno-associated virus vector carrying a ribozyme against MnSOD. This reduced the MnSOD level to 85% and led to the loss of axons and myelin in the optic nerve and the RGCs (563).

### 11.1.23 LHON, Multiple Sclerosis, and Dystonia

While most LHON cases present with isolated optic atrophy, certain pedigrees manifest additional neurologic symptoms, which have suggested additional diseases that may be of mitochondrial origin. Prominent among the LHON-associated symptoms are a multiple sclerosis-like presentation and movement disorders (502,525,564).

An association between some primary LHON mutations and a multiple sclerosis-like demyelinating disease has been repeatedly reported (565). About 1–2% of female patients from LHON pedigrees with the MTND4\*LHON11778A mutation have been diagnosed with multiple sclerosis-like demyelination disease (512,524,566–569). Eight females with the MTND4\*LHON11778A mutation have been described who presented with LHON but subsequently developed clinical and/or neuroradiologic signs consistent with multiple sclerosis (568). A number of other similar cases exhibited an association between either the MTND4\*LHON11778A or the MTND1\*LHON3460A mutations and multiple sclerosis, mostly in females (524,525), but also in males (525,569). Surprisingly, though the MTND4\*LHON11778A mutation accounts for greater than 90% of Japanese LHON cases, no association has been found between this mutation and multiple sclerosis in the Japanese population (570). LHON mutation associations with multiple sclerosis have been evident only when patients are ascertained through LHON presentation (with or without family history) or through multiple sclerosis presentation with early and prominent optic nerve involvement (524). Given the rare population frequency of both LHON and multiple sclerosis diseases, their frequent coincidence probably reflects a related cause (565). It is possible that neuronal cell lysis resulting from the mitochondrial defect releases mitochondrial antigens (571,572) that initiate the autoimmune response (569,573).

Mitochondrial defects can also cause dystonia. Biochemical analysis of an isolated case of idiopathic dystonia, putaminal lesions, and myopathy revealed a partial complex III defect (574). Moreover, complex I defects

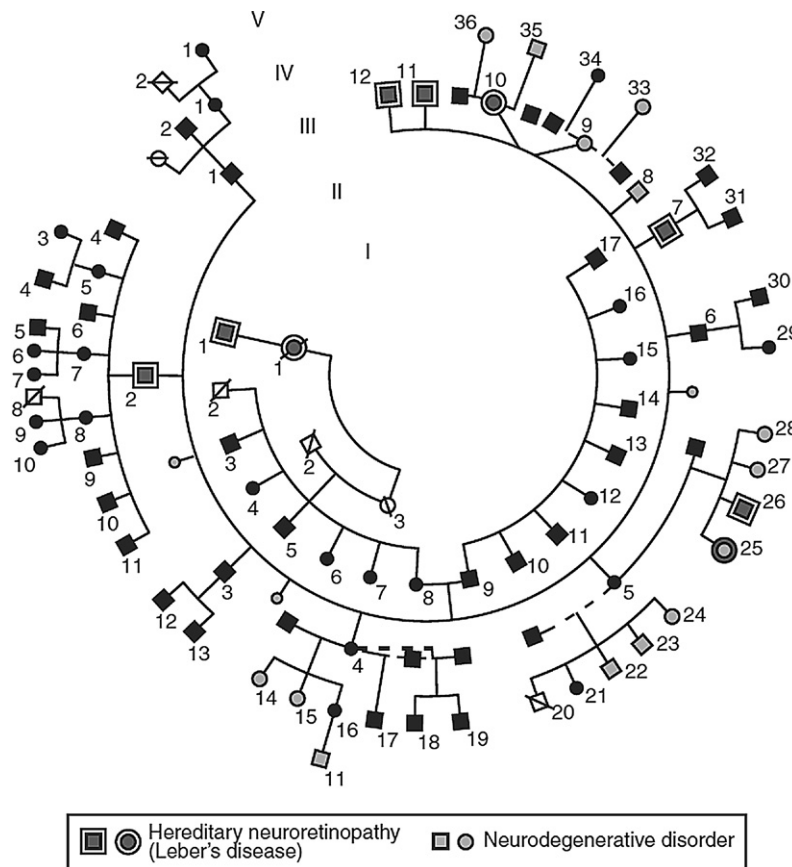

were observed in the platelet mitochondria of a wide variety of dystonia patients, with the average complex I activity of generalized or segmental dystonia patients being reduced 62% while that from focal dystonia patients was reduced 37% (575).

*MTND4\*LHON11778A and Movement Disorders.* A number of LHON pedigrees harboring the MTND4\*LHON11778A mutation include patients which also develop movement disorders. One individual, who lost his vision at 37, developed cerebellar-extra-pyramidal tremor and left-side rigidity associated with bilateral basal ganglia lesions at age 38 (518). A second MTND4\*LHON11778A patient, who suffered visual loss at 23, showed pyramidal signs including spastic paraparesis, inexhaustible patellar and ankle clonus, diffuse muscle weakness, and multiple periventricular and subcortical hyperintensities on magnetic resonance imaging (MRI) compatible with demyelinating disease (523). A third mother and son exhibited ataxia associated with cerebellar and pontine atrophy (576).

*MTND6\*LHON14484C + MTND1\*LHON4160C.* In another large pedigree, the MTND6\*LHON14484C mutation was associated with movement disorders and other neurodegenerative symptoms when present in association with another homoplasmic mutation, MTND1\*LHON4160C, which changes a highly conserved leucine at codon 285 of the ND1 polypeptide to a proline (543). The clinical presentation included sudden-onset optic atrophy with approximately two-fold excess of affected males. Beyond the optic atrophy, there were two neurologic presentations. The first had an onset in the first or second decade of life, starting as a gait abnormality and progressing to include ataxia, spasticity, tremor, dysarthria, posterior column signs, and skeletal deformities. The second had a childhood-onset (5–10 years) severe encephalitic disease occasionally resulting in death; initial signs include headache, convulsions, and abnormal respiration. A novel feature of this later presentation is that some individuals appear to fully recover (577). One branch of the pedigree, with less severe symptoms, was found to have a second homoplasmic mutation, MTND1\*LHON4136G, that was hypothesized to be protective (543). Biochemical analysis of platelet-derived mitochondria from four subjects revealed an 80% average reduction in rotenone-sensitive NADH-CoQ oxidoreductase specific activity (578).

*MTND6\*LDYT14459A.* The MTND6\*LDYT14459A mutation has been shown to cause LHON and/or early-onset generalized dystonia (537,538,564). The MTND6\*LDYT14459A mutation is relatively rare, having been reported in several independent pedigrees (537,538,579). This mutation changes the highly conserved alanine at codon 72 in the ND6 polypeptide to a valine and can manifest as two very different phenotypes: LHON and/or generalized dystonia (Figure 11-9).

**FIGURE 11-9** Hispanic family with maternally inherited LHON and/or dystonia due to the heteroplasmic mtDNA mutation at MTND6\*LDYT14459A. Individuals with LHON experience acute onset optic atrophy and central vision loss, generally as young adults. Individuals with neurodegenerative disease have a much earlier age on onset and experience gait disturbance, rigidity, pseudobulbar syndrome, impaired intelligence, short stature, and frequently infantile bilateral striatal necrosis (IBS) (564).

This mutation has been found to be heteroplasmic in at least some family members in every pedigree studied (see Table 11-1) (537,538). The dystonia generally has an early onset and includes gait disturbance and rigidity of the lower extremities, which advances with age to include the upper extremities (564). Bilateral basal ganglia degeneration (bilateral striatal necrosis) is also a common finding in the dystonia patients.

Evidence for the independent origin of the different family mutations is clear for the MTND6\*LDYT14459A mutation. The mutation was first identified in a large Hispanic family (Figure 11-10), which proved to harbor a Native American haplogroup D mtDNA (537). Subsequently, the same mutation was found in an African American LHON family with a haplogroup L1 mtDNA and in a European dystonia patient with a haplogroup I mtDNA (537,538). Since mtDNA haplotypes of these three families encompass most of the world's mtDNA sequence diversity, it was not possible that the MTND6\*LDYT14459A mutations are related through a common ancestor. Rather, all three MTND6\*LDYT14459A mutations must have arisen recently and independently, a conclusion consistent with the fact that all three families were heteroplasmic. Hence, this mutation must be the cause of this disease (537,538).

Moreover, two additional complex I mutations, MTND4\*LDYT11696G and MTND6\*LDYT14596A, had similar presentations of large maternal pedigrees with LHON and dystonia, the MTND6\*LDYT14596A mutation also being heteroplasmic (548).

While the MTND6\*LDYT14459A mutation has consistently been associated with neurologic disease, the symptoms have differed among patients with different mtDNA backgrounds. This suggests that genetic background might also influence this mutation. In the five-generation Hispanic pedigree with the background mtDNA haplogroup D, among 42 maternal relatives, 19% had LHON, 31% had dystonia and bilateral striatal necrosis, and 2% had both (564). Its penetrance among maternal relatives is about 61%, with 58% of the affected individuals being male, and there is no record of an affected individual recovering. The mean age of onset of dystonia was 4 years, with a range of 1.5–9 years. The motor system was primarily involved and resulted in gait disturbance and rigidity of the lower extremities, which advanced with age to include the upper extremities. Patients also developed pseudobulbar syndrome (swallowing and speech problems), impaired intelligence, short stature, and myopathic features. These symptoms were often associated with bilateral striatal necrosis

**FIGURE 11-10** Magnetic resonance image of the head of a dystonic patient showing bilateral striatal necrosis. The patient is IV24 in Figure 11-9. The left panel is a T1 image (cellular material light). The right panel is a T2 image (aqueous areas light). The lesions are the symmetrical fusiform lesions below and to the left and right of the ventricles (1,11).

(564), the loss of cells in the striatum, putamen, and caudate. In the African American pedigree with mtDNA haplogroup L1, the mother and daughter both developed LHON, but on MRI scan, the daughter was found to have unilateral basal ganglia degeneration. Finally, the singleton European male with haplogroup I mtDNA had dystonia and bilateral striatal necrosis (537,538).

Analysis of MTND6\*LDYT14459A patient skeletal muscle mitochondria has revealed that complex I activity is essentially eliminated (538). In contrast, biochemical analysis of OXPHOS enzymes and respiration in mitochondria isolated from Epstein–Barr virus-transformed lymphoblastoid cell lines of MTND6\*LDYT14459A patients revealed a 55% reduction in complex I specific activity when normalized to citrate synthase or mitochondrial protein (537). This defect could be transferred along with the mutant mtDNAs to  $\rho^0$  lymphoblastoid cells in cybrid experiments (300). In contrast to the greater than 50% reduction in complex I specific activity, the overall mitochondrial respiration rate using complex I substrates was not significantly reduced. This implies that the complex I defect alone is not sufficient to be rate limiting, consistent with respiratory control theory (336,337).

Kinetic analysis of the MTND6\*LDYT14459A complex I defect revealed that the  $V_{\max}$  for NADH is reduced, but the  $K_M$  is not (300). Furthermore, the enzyme activity with increased decyl-ubiquinone (DB), a CoQ<sub>10</sub> analog, showed a maximum activity at 5 mM and then declined as DB was increased to 10 mM, a result in marked contrast to the steady increase in activity seen in the control enzyme over this same concentration range. Finally, there was a marked product inhibition of the enzyme by 5 mM DBH<sub>2</sub>, with the specific activity being inhibited 71%. These data suggest that the MTND6\*LDYT14459A mutation may alter the CoQ<sub>10</sub> binding site of complex I (300). Hence, the MTND6\*LDYT14459A mutation places MTND6 near the CoQ<sub>10</sub> binding site.

The molecular basis of the variable phenotypes associated with the 14459A mutation is puzzling. In the original report, the mother with LHON was heteroplasmic for the mutation while her two dystonic children were homoplasmic (537). This would suggest that variation in the percentage of mutant might result in variable severity of the disease. However, in another pedigree, variably affected maternal relatives were all found to be homoplasmic for the mutation. This was interpreted as indicating that an nDNA factor or factors were influencing the phenotype (579).

#### 11.1.24 Dystonia and Leigh Syndrome Transition for Nd Mutations

The transition from LHON to dystonia to LS is essentially a continuum for complex I polypeptide mutations. The MTND6\*Ldyt/LS14459A mutations can be manifest as LHON, dystonia, or LS (537,580). The MTND1\*DYT3796C mutation has been associated with adult-onset dystonia in a heteroplasmic family (581). Finally, the MTND6\*LS/DYT14487C mutation can present as either dystonia or LS (582). All of these mutations were found to be heteroplasmic, suggesting that one factor in defining the phenotype is the percentage of mutant mtDNAs and thus the severity of the mitochondrial complex I defect (Table 11-2).

Beyond these mutations, the MTND3\*LS10158C, MTND3\*LS/ESOC10191C, MTND3\*LS/Dystonia10197A, MTND4\*LS11777A, and MTND5\*LS12706C mutations all present as LS. All of these mutations were found to be heteroplasmic and have been confirmed in more than one pedigree. Still, the association with LHON and dystonia mutations is apparent. The MTND4\*LS11777A alters the same amino acid (R340S) as the most prevalent LHON mutation MTND4\*LHON11778A (R340H) and the MTND6\*LS/DYT14487C (M63V) mutation is the adjacent codon to the MTND6\*LHON14484C

(M64V) mutation. Therefore, it appears that mild complex I mutations such as MTND4\*LHON11778A and MTND6\*LHON14484C result in LHON, more severe mutations such as MTND6\*LDYT14459A can cause LHON but also dystonia with basal ganglia lesions, and severe complex I defects such as MTND3\*LS10158C, MTND3\*LS/ESOC10191C, MTND3\*LS/Dystonia10197A, MTND4\*LS11777A, MTND5\*LS12706C, and MTND6\*LS/DYT14487C cause earlier onset basal ganglia degeneration and LS.

### 11.1.25 Leigh Syndrome and Retinitis Pigmentosa

Pigmentary retinopathy, neurodegeneration, and LS have been associated with mutations in the mtDNA *ATP6* gene, as well as with mutations in several nDNA genes involved in the assembly of the respiratory complexes.

LS (subacute necrotizing encephalomyopathy) has an average age of onset of about 1.5 years, with a mean duration of illness until death of about 5 years. Clinical manifestations include ataxia, hypotonia, spasticity, developmental delay and regression, optic atrophy, nystagmus, respiratory abnormalities, and ophthalmoplegia. The myopathy is generally non-specific and includes fat accumulations. Occasional patients can show liver involvement, cardiomyopathy, and mitochondrial myopathy (MM) including ragged-red muscle fibers (RRFs) and mitochondria with paracrystalline inclusions, although most patients have normal muscle fiber and mitochondrial morphology. A common observation is the abrupt worsening of the patient's clinical and metabolic status with infections or febrile episodes. A common neuroradiologic finding of end-stage patients is the bilateral degeneration of the basal ganglia, readily observed by computed tomography (CT) scan and MRI analysis. This is the same radiologic manifestation seen for the MTND6\*LDYT14459A mutation (see Figure 11-11). Brain pathology classically reveals basal ganglia necrosis associated with marked vascular proliferation in the brain stem (259).

Current estimates of the proportion of LS cases resulting from the known biochemical and molecular defects (583) include (1) about 18% mtDNA mutations; (2) about 10% pyruvate dehydrogenase (PDH) defects (584–586); (3) about 19% complex I defects (586,587); (4) about 18% complex IV defects, including *SURF1* mutations (158,159,324,588); and (5) about 35% other causes, including complex II (589) and pyruvate carboxylase defects (590). The fact that so many different mitochondrial bioenergetic defects can cause the same lethal phenotype indicates that the clinical manifestations of LS represent the common clinical end point for the more severe mitochondrial OXPHOS defects.

**FIGURE 11-11** mtDNA tRNA<sup>Gln</sup> A4336G mutation associated with late-onset AD and PD.

While the clinical presentation for LS is relatively constant, regardless of the molecular defect, the clinical manifestations of other family members can vary greatly depending on the nature of the genetic defect. Generally, in families with LS resulting from a nuclear gene mutation, the clinical presentation of affected family members is similar to that of the proband. Thus, for X-linked LS due to *PDH E1α* mutations, males are primarily affected and have a similarly severe phenotype. Likewise, LS patients resulting from recessive mutations in nuclear genes will have similar phenotypes in affected family members, with consanguineous marriages being more common. By contrast, LS resulting from heteroplasmic mtDNA mutations will be associated with highly variable clinical presentations among maternal relatives, depending on the percentage of mutant mtDNAs inherited by each family member.

In addition to the five mtDNA complex I mutations that can cause LS, six mutations have been identified in the mtDNA *ATP6* gene and one in the *COIII* gene (see Table 11-2 Panels A and B). The *ATP6* mutations include MTATP6\*NARP/LGHS8993G or C, MTATP6\*LS9176C or G, MTATP6\*LS9185C, and MTATP6\*LS9191C. The MTATP6\*NARP8993G (591–595) and MTATP6\*NARP8993C (596,597) mutations have been observed in multiple independent pedigrees and are well-established causes of LS. These two base changes change the leucine at codon 156 from a leucine to either an arginine or a proline. The MTATP6\*LS/FBSN9176C (598) and the MTATP6\*LS/FBSN9176G (599) mutations result in the substitution of the leucine at codon 217 to either an arginine or a proline, the same changes as seen for the NARP8993C

or G mutations. Finally, the MTATP6\*LGH9185C and MTATP6\*LGH9191C mutations both change a leucine to a proline. All six of the ATP6 mutations associated with LS were heteroplasmic in the respective families. Hence, all of these mutations are likely to cause LS.

The best characterized of the mtDNA ATP6 LS mutations are the MTP6\*NARP/LS8993G or C mutations. These are also the most common. The MTATP6\*NARP8993G mutation was the first described, in a pedigree of maternally inherited neurogenic muscle weakness, ataxia, and retinitis pigmentosa, hence the acronym NARP. MTATP6\*NARP8993G pedigrees are invariably heteroplasmic (591). In the initial three-generation pedigree, the severity of the symptoms varied markedly between individuals and generally correlated with the percentage of mutant mtDNAs harbored by the individual. Neurodegenerative symptoms included generalized seizures, axonal sensory neuropathy, dementia, corticospinal tract degeneration, and cerebellar and brain stem atrophy (591). This latter clinical feature can manifest as olivopontocerebellar atrophy on MRI. One individual presented with mental retardation, macular degeneration, and spicular retinitis pigmentosa (592). Subsequently, families harboring the MTATP6\*NARP8993G mutation were also found to encompass individuals presenting with LS (594,595,600–602).

The variability in clinical presentation of the MTATP6\*NARP8993G and C mutations is primarily due to the replicative segregation of the heteroplasmic mtDNA mutation. In a typically MTATP6\*NARP8993G pedigree, symptoms ranged from mild salt-and-pepper retinitis pigmentosa through olivopontocerebellar atrophy to a pediatric cerebellar ataxia, and lethal LS. Generally, adults with retinitis pigmentosa harbor about 75% mutant mtDNAs, while children with lethal LS have in excess of 90% mutant mtDNAs (592).

The pathophysiology of the MTATP6\*NARP8993G and C mutations has been elucidated through the biochemical analysis of patient mitochondria isolated from cultured cells, and through studies of the mechanism of ATP synthesis by ATPsyn. The MTATP6\*NARP8993G and C mutations change the highly conserved leucine 156 in the ATP6 polypeptide to an arginine or a proline, respectively. Biochemical analysis of the MTATP6\*NARP8993G mutation in patient lymphoblasts or fibroblasts has revealed a 30–50% reduction in the rate of ATP synthesis (600,601,603). Moreover, in patient lymphoblasts and in their trans-mitochondrial cybrids, there was a 30–40% reduction in the rate of maximal (state III) respiration and a comparable reduction in ADP:O ratios (301). Finally, the MTATP6\*NARP8993G mutation has been found to significantly increase mitochondrial ROS production (604), which is consistent with other results that demonstrate that inhibition of mitochondrial ATP synthesis results in hyperpolarization of  $\Delta P$  and elevated mitochondrial ROS production (605).

Correlating the position and nature of the amino acid changes caused by the MTATP6\*NARP8993G and C mutations with recent data on the rotor–stator mechanism of ATPsyn indicates that the MTATP6\*NARP8993G and C mutations must compromise the ATPsyn proton channel. The highly conserved leucine at ATP6 amino acid 156 is analogous to the *Escherichia coli* amino acid 207. This forms the base of  $\alpha$ -helix 4 in the bacterial protein subunit a, the homolog of ATP6. Leucine 156 (bacterial 207) is on the same face of the helix as arginine 159 (bacterial 210). Arginine 159 (bacterial 210) is thought to provide the positive charge that pulls the negatively charged, deprotonized glutamate 58 (bacterial aspartate 61) from the matrix-space half-proton channel around to the intermembrane-space half-proton channel. Arginine 159 (bacterial 210) is displaced from the glutamate 58 (aspartate 61) so as to provide attraction, without forming a salt bridge and blocking rotation of the ATP9 (subunit c) protein wheel. However, conversion of leucine 156 to arginine adds a second positive charge on the ATP6 (a)–ATP9 (c) interface, and conversion of leucine 156 to proline disrupts the  $\alpha$ -helix and presumably the interface between ATP6 (a) and ATP9 (c). Hence, both mutations would stall the rotor, block the proton channel, and inhibit ATP synthesis.

The three remaining ATP6 mutant missense mutation sites (MTATP6\*FBSN9176C/G, MTATP6\*LS9185C, and MTATP6\*LS9191C) share similarities with the MTATP6\*LS8993G/C mutations. For example, the MTATP6\*LS/FBSN9176C/G mutation (L217P) is 61 codons away from the MTATP6\*NARP8993G and C mutations. In *Escherichia coli*, mutations in the c subunit (ATP9) that change aspartate 61 to glycine can be suppressed by mutations in the a subunit (ATP6) at Ala 217, Ile 221, and Leu 224. Moreover, mutations at Gly 218 and His 214 of protein a (ATP6) result in uncoupling proton translocation from ATP synthesis, while the double mutant Gly 218 to Lys plus His 245 to Gly restores activity (172). This implies that the region of human ATP6 around amino acid 197 (bacteria 245) may also be important in coupling the proton gradient to ATP synthesis. Thus, the MTATP6\*FBSN9176C mutation affecting ATP6 amino acid 217 (bacterial 256) is adjacent to bacterial His 245 and hence might alter the integrity of the ATPsyn proton channel. Furthermore, since all of the LS mutations convert a leucine to either an arginine or a proline, it seems likely that all of these mutations may affect the ATPsyn proton channel and thus coupling efficiency and ATP synthesis.

Finally, one mtDNA mutation associated with LS was found in the COIII gene, MTCO3\*LS9537insC. This resulted in a frameshift, destroying the protein. Moreover, the mutation was homoplasmic in the patient (606). This case confirms that the final common end point for the most severe missense mutations appears to be LS.

### 11.1.26 Encephalomyopathies and Multisystem Disorders

Mitochondrial encephalopathies associated with mtDNA polypeptide mutations encompass a diverse array of symptoms associated with mitochondrial defects that affect the primary energy-utilizing tissues, including the central nervous system, heart, and muscle. Furthermore, the muscle generally exhibits MM with RRFs. Patients with mitochondrial encephalomyopathies can harbor mitochondrial polypeptide mutations, although these types of symptoms have more commonly been reported in patients harboring mtDNA protein synthesis (tRNA or rRNA) mutations. Several clusters of symptoms occur together in the encephalomyopathies, but the *mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes* (MELAS) syndrome is the cluster most commonly associated with mitochondrial polypeptide mutations (see [Table 11-2](#) Panels A and B).

Patients with a MELAS presentation have been reported to have 12 different mutations in complex I subunits as well as one *COIII* and one *CYTB* mutation. All of the reported mutations have been missense mutations except the *CYTB* mutation, and all have been heteroplasmic, indicating new pathogenic mutations.

Complex I subunit mutations have been reported in the ND1, 4, 5, and 6 subunits (see [Table 11-2](#) Panels A and B). For the MTND1 subunit, the MTND1\*MELAS3308C mutation eliminated the methionine start codon. The MTND1\*MELAS G3376A, G3697A, G3946A, and T3949C mutations affect other amino acids throughout the ND1 polypeptide. The MTND4\*MELAS11084G (T109A) variant has also been associated with a MELAS pedigree ([607](#)), but more recent studies suggest that this may be an Asian polymorphism ([608](#)). However, the MTND5\*MELAS A12770G, A13045C, A13084T, G13513A, and A13514G mutations all make quite significant polypeptide changes and thus are likely to cause the disease. Finally, the MTND6\*MELAS14453A (A74V) mutation ([609](#)) is three codons away and results in the same amino acid change as the well-established LHON and dystonia mutation, MTND6\*LDYT14459A (A72V) ([537,538](#)), which is associated with basal ganglia degeneration. The most common cause of the MELAS syndrome is the tRNA<sup>Leu(UUR)</sup> mutation, MTTTL1\*MELAS3243G, which inhibits mitochondrial protein synthesis and predominantly results in complex I deficiency (see [Section 11.1.32](#)). Hence, MELAS symptoms probably result from a particularly severe complex I defect.

The MTCYB\*MELAS/PD14787del4 ([610](#)) and MTCO3\*MELAS/PEM/NAION9957C (F251L) mutations ([611,612](#)) currently stand alone among the “MELAS” polypeptide mutations since they are the only ones that do not directly affect complex I. Furthermore, the symptoms of these patients are more complex and less stereotyped. For example, the MTCYB\*MELAS/

PD14787del4 boy with a 4-bp mtDNA deletion in the *CYTB* gene first manifested fine motor coordination problems at 6 and showed fatigue and regressive behavior by 14, along with tremor, stimulus-responsive myoclonus, lactic acidosis, cardiac conduction defects, and diffuse cerebral and cerebellar atrophy. At 20, he was experiencing short episodes of disturbed consciousness, episodes of status epilepticus, tonic-clonic seizures, a stroke-like episode associated with cortical blindness, and parieto-occipital cerebral infarcts. Muscle biopsy revealed a complex III defect associated with a single RRF and aggregates of subsarcolemmal mitochondria. Analysis of his mtDNA cytochrome *b* gene revealed that the 14787del4 mutation resulted in a frameshift from codon 13, which terminated the protein at codon 50. In muscle, ~95% of the mtDNAs were mutant, while in blood, hair follicles, oral mucosa, and fibroblasts about 60% of the mtDNAs were mutant ([610](#)).

Multiple severe mtDNA polypeptide mutations have been associated with more complex encephalomyopathies and multiple system disorders. Encephalomyopathies and multiple system disorders associated with COI include MTCO1\*EPLP6489A (L196I), MTCO1\*EM6930A (G343Ter), and MTCOI\*EM6015del5 (frameshift); those associated with COII include MTCO2\*ENMM 7587C (M1T), MTCO2\*MS7896A (W104Ter), and MTCO2\*EM8042del2 (M153Ter); and those associated with COIII include MTCO3\*EM9952A (W248Ter). Encephalomyopathies and multiple system disorders associated with ATP6 include MTATP6\*LA9205del2 (Ter227M), and those associated with the cytochrome *b* mutants include MTCYB\*MS15579G (Y278C) and MTCYB\*SOD14849C (S39P) (see [Table 11-2](#) Panels A and B).

An example of a chain termination mutation that results in a multisystem disorder is the MTCO1\*MSD6930A mutation. This mutation was found in a 21-year-old woman who developed bilateral cataracts at 3 years; sensorineural hearing loss at 7; and muscle weakness with 90% of muscle fibers being COX deficient, myoclonic epilepsy, cerebellar ataxia, optic atrophy, cerebellar atrophy, bilateral basal ganglion degeneration, lactic acidosis, and elevated serum creatine kinase by age 21. Molecular analysis revealed that the G6930A mutation created a stop codon and deleted the last 170 amino acids of COI. The mutation was heteroplasmic in blood (27%), muscle (75%), and myoblasts (33%), but was not detected in the blood of the mother or sister. Cybrids harboring the mutation had reduced growth rates on galactose and diminished COX activity ([613](#)).

The second COI mutation patient had a very different phenotype. She exhibited upper motor neuron disease at 1 year that progressed to spastic paraparesis at 29 years. MRI revealed bilateral corticobulbar track lesions, muscle histochemistry revealed RRFs and mitochondrial COX deficiency, and physiologic studies mild lactic acidosis. Molecular analysis revealed the deletion of one

of two adjacent 5-bp repeats encompassing nps 6015 through 6024. This generated a stop codon six codons downstream from the deletion, resulting in a 42-amino acid product instead of the 513-amino acid product. The patient's muscle was heteroplasmic for the mutation, 47% and 69% on successive muscle biopsies; the muscle of the patient's mother and three sisters lacked the mutation. Single muscle fiber mutation analysis revealed that normal fibers were 29% mutant, COX-deficient fibers 38% mutant, COX-negative fibers 69% mutant, and RRFs 91% mutant (614).

Another patient developed progressive ataxia at 5 years, and was wheelchair bound with mild distal wasting, cognitive impairment, optic atrophy, pigmentary retinopathy, and decreased color vision by age 25 years. A muscle biopsy revealed he had 15% RRF and 80% COX-negative fibers. Molecular analysis revealed a heteroplasmic T7587C mutation in the second base of the initiation codon of the *COII* gene, converting it from a methionine to a threonine. The mutation was present in 91% of muscle, 89% of fibroblast, and 36% of blood samples. In single fiber analysis, COX activity was severely reduced in fibers with over 55–65% mutant mtDNAs (615). In this case, destruction of the methionine initiation codon presumably eliminated the COII protein, thus accounting for the severe phenotype.

Another patient with a COII stop codon mutation collapsed after vigorous exercise at 17 years, experiencing confusion and headache. She developed episodic myalgia by age 21 that progressed to increased fatigue and regular headaches following three pregnancies. This progressed to periodic stuporous states with elevated lactate and creatine kinase and frequent migraine-type headaches. Muscle histology revealed COX-negative fibers but no RRFs, and muscle mitochondrial COX activity was 20% of control while cytochrome *aa<sub>2</sub>* content was 17%. Molecular analysis revealed a G9952A mutation in the *COIII* gene, which changed a tryptophan codon to a stop codon 13 amino acids from the C-terminal end. The mutation was heteroplasmic, being present in 57% of the mtDNAs in two independent tests. In COX-negative fibers the proportion of mutant was 56%, but in COX-positive fibers it was 10% (616).

### 11.1.27 Mitochondrial Myopathy and Ragged Red Muscle Fibers

A wide spectrum of mitochondrial base substitution mutations have been identified that cause MM. MM involves progressive muscle weakness in association with a distinctive muscle pathology detected by Gomori modified trichrome. Trichrome staining reveals turquoise muscle fibers that tear on sectioning and have aggregates of red-staining material, generally in the subsarcolemmal regions. This red material is aggregate of highly abnormal mitochondria, often containing precipitates, membrane whorls, or paracrystalline arrays (see Figure 11-9). The paracrystalline structures contain mitochondrial

creatine phosphokinase (8,617). Such muscle fibers are called *ragged red muscle fibers*.

MM associated with RRFs is most commonly observed in patients harboring pathogenic base substitution mutations in rRNAs or tRNAs, such as in MERRF and MELAS pedigrees. However, MM has also been found to be associated with mutations in the *CYTb* gene (618).

Progressive muscle weakness, exercise intolerance, and MM have been repeatedly linked to deleterious mutations in the mtDNA *CYTb* gene, all of which have been heteroplasmic and many in isolated cases. Thirteen *CYTb* mutations have been reported, including five missense mutations: MTCYB\*EXIT14846A (G34S), MTCYB\*EXIT15197C (S151P), MTCYB\*EXIT15497A (G251S), MTCYB\*EXIT15615A (G290D), and MTCYB\*MM15762A (G339E). Seven additional chain termination mutations have been identified—MTCYB\*MM15059A (G190Ter), MTCYB\*EXIT15084A (W113Ter), MTCYB\*EXIT15150A (W135Ter), MTCYB\*EXIT15168A (W141Ter), MTCYB\*EXIT15242A (G166Ter), and MTCYB\*EXIT15723A (W326Ter)—as well as one 24-np deletion (MTCYB\*EXIT15498del24) (see Table 11-2).

One example of a case harboring a *CYTb* missense mutation is a 29-year-old male with progressive muscle weakness and exercise intolerance associated with complex III deficiency. This individual had a MTCYB\*EXIT15615A mutation, which changed the highly conserved glycine 290 to an aspartate (G290D). The proband had 90% mutant mtDNAs in his muscle, but no mutant in his blood. The blood of his mother and sister also lacked the mutant mtDNA (619).

Two representative examples of MM and exercise intolerance resulting from *CYTb* chain termination mutations are MTCYB\*EXIT15242A and MTCYB\*MM15059A. The MTCYB\*EXIT15242A nonsense mutation case was a 38-year-old female with progressive muscle weakness, severe exercise intolerance, lactic acidosis, and a complex III deficiency. Using <sup>32</sup>P-labeled nuclear magnetic resonance (NMR), she was found to have a marked inhibition of recovery in her muscle PCr:Pi ratio following exercise. The patient's muscle mtDNAs were found to be 85% mutant, while her blood and that of her maternal relatives were homoplasmic wild type (620–623). In an effort to circumvent the block in her ETC, this patient was treated with ascorbate and menadione. This metabolic therapy substantially improved the patient's capacity for PCr:Pi recovery following exercise (622). This patient was reanalyzed and, in addition to exercise intolerance, developed a mitochondrial encephalomyopathy over the years (624).

The MTCYB\*MM15059A mutation occurred in a 27-year-old male with progressive muscle weakness, exercise intolerance, and episodic myoglobinuria. He had a marked decrease in complex III and RRFs, which were SDH and COX positive. His cytochrome *b* protein was truncated by conversion of the glycine 190 codon to

a stop codon, eliminating the terminal 244 amino acids of the protein. The patient was heteroplasmic, with 63% mutant in muscle but no mutant in blood. Furthermore, his RRFs were about 81% mutant while his non-RRFs were about 35% mutant. This mutation could not be detected in his mother or sister (625).

Five cases of MM and/or exercise intolerance have also been linked to mutations in the *MTCOI*, *MTCOII*, and *COIII* genes, all heteroplasmic. Two chain termination mutations have been reported in the *COI* gene associated with MM, rhabdomyolysis, and myoglobinuria. The *MTCO1*\*EXIT5920A mutation truncated the protein at codon 6 (W6Ter) (503), while the *MTCO1*\*MM6708A mutation truncated the protein at codon 269 (G269Ter) (545). Two missense mutations have been reported in *COII* that manifested as MM and exercise intolerance, *MTCO2*\*MM7671A (M29K) (832) and *MTCO2*\*MM7989C (L135P) (652). Finally, an in-frame deletion of 15 bp was reported in the *COIII* genes in a patient with exercise intolerance (626).

An example of the presentation seen in *COII* mutation cases is given by the 4-year-old boy with the *MTCO2*\*MM7671A mutation (M29K). This boy had a history of muscle weakness and fatigue. He was thin and had elevated serum lactate. Histochemical analysis revealed severe COX deficiency in 97% of fibers, though no RRFs on trichrome stain. Other clinical and physiologic findings were normal. Polarographic analysis of muscle mitochondria revealed a COX deficiency, and histochemical studies revealed a severe reduction in COII. Molecular analysis revealed that the T7671A mutation was heteroplasmic in muscle, but was not detected in myoblasts. It was present at 4.5–6% in peripheral blood (627).

The patient with the *COIII* mutation in-frame deletion was a 15-year-old female with periodic muscle cramps, elevated creatine kinase, and myoglobinuria associated with decreased caloric intakes. Histochemical analysis revealed many RRFs with 64% COX-negative fibers. Muscle mitochondrial COX activity was reduced 86% and cytochrome *aa<sub>2</sub>* was also reduced. Molecular analysis revealed a 15-bp deletion in *COIII* removing the intervening sequence between two direct repeats. This mutation was heteroplasmic, with the mutation being present at 92% in muscle and 1% in leukocytes and absent in fibroblasts. In muscle, COX-positive fibers had 25% mutant mtDNAs, COX-deficient fibers 97%, and COX-deficient RRFs 99%. The mutant mtDNA was not detected in the mother's leukocytes (626). These observations demonstrate that heteroplasmic intra-genic polypeptide mutations can result in a wide spectrum of the symptoms associated with mitochondrial encephalomyopathies.

Finally, two complex I subunit mutations have been found to cause MM. The chain termination mutation *MTND4*\*EXIT11832A (W358Ter) was associated with exercise intolerance (628), while the *MTND4*\*CPEO11232C (L140P) missense mutation

caused chronic progressive ophthalmoplegia with MM (629).

In total, these cases suggest that severe polypeptide mutations can cause isolated cases of severe MM. Such mutations are heteroplasmic, suggesting that they arose recently in the female germline.

### 11.1.28 Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy can be a clinical manifestation of a variety of mtDNA mutations, though in some patients it is the presenting feature. Two patients with *CYTB* mutations have been reported with MM and cardiomyopathy. Both of the reported cases have been missense mutations: *MTCYB*\*HCM15243A (G166E) (630) and *MTCYB*\*HCM15498A (G251D) (631).

### 11.1.29 Deafness and Sensorineural Hearing Loss

Sensorineural hearing loss is a common clinical manifestation of mtDNA mutations, both protein synthesis and polypeptide mutations. Six polypeptide mutations have been reported to be associated with deafness, four in *COI*, one in *COII*, and one in *ND6*. The four *COI* mutations are particularly interesting because they all affect the stop codon at the end of the *COI* polypeptide, codon 514. Mutations *MTCO1*\*DEAF7443G (Ter514G), *MTCO1*\*DEAF7445C (Ter514S), and *MTCO1*\*SNHL/LHON7444A (Ter514K) suppress the stop codon and result in the extension of the polypeptide by three amino acids (see Table 11-2 Panel B). The *MTCO1*\*SNHL/LHON7444A (Ter514K) mutation might also increase the risk for developing LHON (544). The fourth *COI* mutation, *MTCO1*\*SNHL7445G (Ter514Ter), changes the sequence of the stop codon and has been associated with deafness in several studies. The pathophysiologic effect of these variants is unclear. However, the fact that a clinical phenotype results even when a stop codon is retained suggests that the effect may not be in the function of the *COI* protein but perhaps in the processing of the polycistronic RNA transcript and thus the adjacent serine tRNA.

The *MTCO2*\*SNHL8108G (I175V) and *MTND6*\*SNHL14340T (V112M) are both missense mutations (632). Their pathophysiologic effect remains to be determined.

### 11.1.30 Movement Disorders and Dementias

Three missense mutations have been reported to be associated with AD and (PD). The *MTND1*\*ADPD3397G mutation was found associated with the *MTTQ*\*ADPD4336C mutation and changes a highly conserved amino acid (633). The *MTND2*\*AD5460A/T mutations have been associated with AD through populations

studies (634), but this association has been questioned (635,636).

### 11.1.31 Diseases Resulting from Intragenic tRNA and rRNA Mutations

Intragenic mutations that alter mtDNA tRNA and rRNA genes and cause disease due to inhibition of mitochondrial protein synthesis are referred to as mtDNA protein synthesis defects. A defect in mitochondrial protein synthesis has the capacity to retard the synthesis of all of the mtDNA-encoded polypeptides, resulting in the inhibition of complexes I, III, IV, and V, but not II. However, since the largest and most numerous mtDNA-encoded subunits belong to complex I (7 subunits) and complex IV (3 subunits), intermediate-severity protein synthesis defects most commonly affect these enzymes.

Unlike mtDNA mutations that inactivate a particular polypeptide and result in more stereotypic clinical presentations, protein synthesis mutations are frequently associated with multisystem disorders. Their variable clinical phenotypes can be additionally complicated by variation in the mutant mtDNA heteroplasmy.

The most common clinical manifestation of mitochondrial protein synthesis mutations is MM involving RRF and abnormal mitochondria, frequently with paracrystalline precipitates. For some mtDNA protein synthesis mutations, this may be the primary clinical presentation. For protein synthesis mutations that result in multisystem encephalomyopathies at high percentages of mutant, patients with lower percentages of mutant mtDNA might only manifest MM.

The variability in clinical presentations of mtDNA protein synthesis mutations was already apparent in the first mtDNA protein synthesis mutation described, the MTTK\*MERRF8344G mutation, causing maternally inherited MERRF syndrome (5,6). Variability in clinical presentation is also the hallmark of the most common mtDNA protein synthesis mutation, the MTTL1\*MELAS3243G mutation, causing MELAS syndrome (326). At 10–30% mutation, the MTTL1\*MELAS3243G mutation causes diabetes mellitus with or without deafness. However, at higher percentages of mutant the same mutation can cause chronic progressive ophthalmoplegia, cardiomyopathy, or the complete MELAS syndrome (412).

In this section, we discuss the mitochondrial protein synthesis mutations classified based on the most common clinical presentation seen when the patients harbor a high percentage of the mutant mtDNA.

### 11.1.32 Mitochondrial Encephalomyopathies and Multisystem Disorders

The mitochondrial encephalomyopathies combine MM with a complex array of neurodegenerative disease

symptoms. A variety of mtDNA tRNA mutations have been reported to result in these combined muscle and brain degenerative diseases (Table 11-3 Panels A and B). These mitochondrial protein synthesis mutations often affect multiple tissues, although the central nervous system, heart, skeletal muscle, kidney, and endocrine system are most often compromised. The nature and extent of the clinical symptoms can vary markedly based on the nature of the mutation and the degree of heteroplasmy in the affected tissues. The more severe protein synthesis mutations are frequently associated with elevated serum, urine, or cerebrospinal fluid lactate, alanine, and/or other organic and amino acids. Mitochondrial encephalomyopathies can either be stereotypical in their presentation, such as Leigh, MERRF, and MELAS syndromes, or they can be associated with a diverse array of symptoms.

Three mtDNA tRNA mutations have been associated with LS (MTTV\*LS1624T, MTTV\*1644T, and MTTW\*LS5537insT). In addition, other mtDNA tRNA mutation pedigrees can occasionally contain a family member who presents with LS. This has been observed in individuals harboring the protein synthesis mutations MTTK\*MERRF8344G (637,638) and MTTL1\*MELAS3243G (259) (see Table 11-3 Panels A and B).

However, LS is a relatively rare presentation for mtDNA protein synthesis gene mutations. By far the most common presentations are MERRF syndrome, most commonly caused by the MTTK\*MERRF8344G mutation (5,6), and MELAS syndrome, most commonly the result of the MTTL1\*MELAS3243G mutation (326). A description of the clinical variability of these common mutations will provide a sense of the complexities in diagnosing mitochondrial protein synthesis diseases.

MERRF-like pedigrees have been associated with nine different tRNA mutations. Classical MERRF syndrome has been observed and has been associated with seven different mtDNA tRNA mutations. By far the most common is the MTTK\*MERRF8344G mutation (5,6). Three other tRNA<sup>Lys</sup> mutations have also been linked to MERRF syndrome, specifically altering positions T8356C, G8361A, and G8363A (see Table 11-3 Panels A and B). Other tRNA mutations associated with MERRF syndrome have been reported in the tRNA<sup>Phe</sup> (611A), tRNA<sup>Leu(UUR)</sup> (3255A), and tRNA<sup>His</sup> (12147A), while related phenotypes have been observed in tRNA<sup>Val</sup> (1606A) and tRNA<sup>Asp</sup> (7543G) (see Table 11-3 Panels A and B).

MERRF syndrome typically presents with myoclonic epilepsy and MM. Myoclonic epilepsy is an uncontrolled periodic jerking, frequently beginning focally but progressing over the course of the disease to generalized cyclic muscle contractions. These are associated with high-amplitude voltage spikes on electromyographic analysis and with marked slowing of electroencephalographic wave activity (4,639).

While a pedigree might first be identified by a patient with MERRF syndrome, careful clinical examination frequently reveals individuals along the maternal lineage with a variety of other less severe clinical presentations. These can include subclinical electrophysiologic changes such as hyperexcitable visual evoked response and clinically related slowing and variability in somatosensory evoked response, sensorineural hearing loss, ataxia, renal dysfunction, MM, diabetes, cardiomyopathy, and dementia (4,259,639,640). Anterior and posterior cervical lipomas are also frequently seen in severely affected MERRF patients (259,638,641).

MERRF syndrome is most frequently associated with mutations in the tRNA<sup>Lys</sup> gene. Approximately 80–90% of cases result from the MTTK\*MERRF8344G mutation (4,642), while many of the remaining cases are due to the MTTK\*MERRF8356C mutation (643,644). Occasionally, other tRNA mutations can also result in MERRF syndrome, most notably the MTTL1\*MELAS3243G mutation (645). The MTTK\*MERRF8344G mutation changes a highly conserved A to a G in the TΨC loop of tRNA<sup>Lys</sup> gene, while the MTTK\*MERRF8356C converts a T to a C, disrupting an A–U base pair at the base of the TΨC loop. MERRF mutations are heteroplasmic in families.

A detailed analysis of the associations between clinical presentation, biochemical defect, and mtDNA genotype in one large MTTK\*MERRF8344G family revealed a strong correlation between genotype and phenotype, when age was taken into account (6,333,642). Among the 19- to 24-year-olds of this family, an individual with 15% normal mtDNAs in skeletal muscle had normal muscle mitochondrial energy capacity as determined by the anaerobic threshold in exercise stress tests ( $\theta_{an}$ ), normal OXPHOS enzyme activities, and normal phenotype, exhibiting only mild electrophysiologic changes. By contrast, 20-year-olds with only about 5% normal muscle mtDNA had reduced mitochondrial energy capacity and more severe symptoms, with the proband having less than 25% normal muscle energy capacity and the complete MERRF syndrome. Similarly, maternal relatives in the 40- to 50-year age range who retained about 10% normal mtDNAs showed higher muscle energy capacity and milder phenotypes than comparably aged individuals with half that level of normal mtDNAs, with the latter exhibiting reduced energy metabolism and more severe symptoms. Finally, among two maternal relatives in the 60- to 70-year range, an individual with 27% normal mtDNAs had significant residual mitochondrial energy capacity and mild to moderate symptoms, while another individual with 16% normal mtDNAs had complete MERRF syndrome. Most striking, however, was the difference between the 19-year-old with 15% normal mtDNAs and no clinical symptoms and the 60-year-old with 16% normal mtDNAs and severe disease. The much more severe clinical problems of the older subject with the sample mtDNA genotype reflect a general feature of

mtDNA diseases: They showed a delayed onset and they progressed with age.

A severe mitochondrial protein synthesis defect has been found to be associated with the MTTK\*MERRF8344G mutation in patient skeletal muscle (646), myoblasts/myotubes (647,648), and fibroblasts (649). The translation defect results in a general reduction in the rate of protein synthesis most affecting the larger mitochondrial polypeptides, together with the generation of abnormal translation products. This results from a 50% to 60% decrease in tRNA<sup>Lys</sup> aminoacylation (650). Accompanying the translation defect is a reduction in mitochondrial O<sub>2</sub> consumption and ETC enzyme activity (6,649). Protein synthesis abnormalities and OXPHOS defects have been unambiguously assigned to both the MTTK\*MERRF8344G and MTTK\*MERRF8356C mutations by cybrid transfer using both patient myoblasts (MTTK\*MERRF8344G only) (648) and fibroblasts (651). It is postulated that the reduction of mitochondrial protein synthesis results in lowering of the steady-state levels of OXPHOS enzyme complexes, perhaps due to premature termination of translation at lysine codons.

MELAS syndrome has now been associated with 13 different mtDNA tRNA mutations, 8 of which are found in the tRNA<sup>Leu(UUR)</sup>. In addition, the MELAS presentation has been associated with tRNA<sup>Phe</sup>, tRNA<sup>Val</sup>, and tRNA<sup>Gln</sup> mutations and one of the rare instances of a heteroplasmic 16S rRNA mutation (see Table 11-3 Panels A and B).

MELAS pedigrees are often ascertained through a patient who has experienced a stroke-like episode. Generally this first occurs between the ages of 5 and 15 years, though it can occur any time from infancy to adulthood. Muscle biopsy of such patients usually reveals MM (652). In addition, maternal relatives can exhibit a wide variety of complex clinical problems involving the central nervous system, muscle, heart, renal, and endocrine systems. MELAS syndrome can be caused by a variety of mtDNA tRNA mutations, most of which are in the tRNA<sup>Leu(UUR)</sup> gene. The MTTL1\*MELAS3243G (653,654) mutation is by far the most common. Additional MELAS mutations include MTTL1\*MELAS3244A (655), MTTL1\*MELAS3252G (656), MTTL1\*MELAS3258C (657), MTTL1\*MELAS3256T (658), MTTL1\*MELAS3271C (659), and MTTL1\*MELAS3291C (660,661). In addition to these mutations, other tRNA mutations, including the MTTK\*MERRF8344G mutation, can give a MELAS-like phenotype. MELAS mutations have also been reported in tRNA<sup>Phe</sup> (G583A), tRNA<sup>Val</sup> (G1642A), and tRNA<sup>Gln</sup> (G4332A) and in the 16S rRNA (C3093G) (see Table 11-3 Panels A and B). Some mtDNA tRNA mutations, such as the MTTL1\*MELAS3256T and the MTTS1 \*MERME7512C mutations, can give rise to a MERRF/MELAS overlap syndrome (658,662,663). The fact that complex I missense mutations give MELAS

syndrome and that defects in mitochondrial protein synthesis that would inhibit the expression of the seven complex I subunits all give MELAS syndrome provides convincing evidence that MELAS syndrome is the product of severe complex I deficiency.

Like the MTTK\*MERRF8344G mutation, both the MTTL1\*MELAS3243G and the MTTL1\*MELAS3271C mutations result in a marked defect in mitochondrial protein synthesis. This is most dramatically demonstrated in cybrid studies performed with patient myoblasts (664,665) and fibroblasts (665,666). Invariably, the MELAS mutations cause a generalized reduction in the rate of mitochondrial protein synthesis of up to 70% (664) and a concomitant reduction in the steady-state levels of mitochondrial proteins when the proportion of mutant mtDNAs is greater than about 94%. Cybrid cell lines with greater than 94% MTTL1\*MELAS3243G and MTTL1\*MELAS3271C mutant mtDNAs can also have oxygen consumption rates reduced up to 70% (664–666), although to a lesser degree in the MTTL1\*MELAS3271C cybrid lines (666). Histologic and immunohistochemical analysis (667) has revealed a reduction in the levels of gene products in patient skeletal muscle harboring the MTTL1\*MELAS3243G mutation. The translation of the larger mitochondrial-encoded gene products appears to be most severely compromised, and preferential defects in complex I and/or complex IV are frequently observed in skeletal muscle (653,668–670) for MTTL1\*MELAS3243G patients.

The actual pathophysiologic mechanism by which the MTTL1\*MELAS3243G mutation results in MELAS remains unclear. Because the 3243 nucleotide lies within the transcriptional terminator sequence for the rRNA genes, it is possible that this mutation perturbs the transcriptional processes. In *in vitro* experiments, diminished affinity for the mitochondrial transcription terminator protein (mTERM) for the mutant terminator sequence has been reported (671). This was related to an impairment of transcript termination for the 16S rRNA gene, and possibly altering the rRNA:mRNA ratio. Some studies have confirmed a reduced affinity of mTERM for the mutant termination sequence (664), and in some cases reduced transcriptional termination (672), but others have found no evidence of abnormal termination, altered rRNA production, or a MELAS-specific perturbation in rRNA:mRNA ratios (664,667,672–674). Moreover, the MTTL1\*MELAS3271C mutation is not found within the transcription. A non-protein coding CR polymorphism at T16189C has also been reported to predispose to type 2 diabetes (675), though this association has been challenged (676).

The primary cause of MELAS syndrome may be altered mitochondrial translation. One proposal is that the MTTL1\*MELAS3243G and MTTL1\*MELAS3271C mutations alter transcript processing. Cybrids harboring these mutants have been reported to accumulate RNA processing intermediate RNA 19, which

corresponds to a transcript containing the contiguous 16S rRNA + tRNA<sup>Leu(UUR)</sup> + ND1 genes (665,666).

The spectrum of clinical manifestations associated with maternal relatives of MELAS patients is best characterized for the MTTL1\*MELAS3243G mutation (259,660,669,677,678). In addition to strokes, patients harboring this mutation can be prone to migraine headaches and focal or generalized seizures, ataxia, myoclonus, sensorineural deafness, retinopathy, and dementia. They can experience fatigability, myopathy, renal failure, myalgia, and ophthalmoplegia, and develop hypertrophic or dilated cardiomyopathy and cardiac conduction defects. In rare cases, this mutation has also been associated with peripheral neuropathy plus rhabdomyolysis (679), demyelinating polyneuropathy (680), and ischemic colitis (681). By far the most dramatic alternative phenotype of the MTTL1\*MELAS3243G mutation is type 2 diabetes mellitus with or without sensorineural hearing loss (682). It is now well established that diabetes mellitus is by far the most common clinical presentation of the MTTL1\*MELAS3243G mutation (see below).

The pathophysiology of mitochondrial stroke is quite different from that of the stroke associated with vascular occlusion. CT and MRI analysis frequently reveals infarcts in the posterior temporal, parietal, and occipital lobes. These frequently overlap several large vessel vascular beds, and can be transitory, often resolving along with the clinical signs. It has been hypothesized that these infarcts are due to transient OXPHOS dysfunction within the brain parenchyma, rather than vascular events (259,652,683). Alternatively, they might be the product of vascular spasm, with the contraction extending along an extended region of the cortical vasculature, inhibiting blood flow and causing ischemia. This hypothesis is supported by extensive postmortem analysis of the cortical vasculature of MTTL1\*MELAS3243G and MTTL1\*MELAS3271C mutation patients (660,674,684,685). Histochemical and electron microscopic analyses of MELAS patient vessels have revealed accumulations of abnormal mitochondria in the vascular endothelial cells and vascular smooth muscle cells. The mitochondria are frequently pycnotic, contain mitochondrial occlusions, and stain extensively for SDH (complex II), which is associated with a large increase in both mutant and normal mtDNAs (653,660,674,686,687). The increased complex II activity implies a compensatory induction in mitochondrial biogenesis in response to a vascular cell OXPHOS deficiency.

Patients with mitochondrial protein synthesis defects resulting from the MTTL1\*MELAS3243G mutation or mtDNA deletions show striking increases in immunohistochemical staining of their RRFs for the mitochondrial MnSOD and weakly increased staining for the cytosolic copper/zinc superoxide dismutase (Cu/ZnSOD). Moreover, the MnSOD staining is strongly positive in the subsarcolemmal region and shows a coarsely granular,

reticular, or diffuse pattern between the myofibrils. Interestingly, the MELAS RRFs that are MnSOD positive are frequently still COX positive, while the CPEO MnSOD-positive fibers are generally COX negative (688). Hence, mitochondrial protein synthesis defects are associated with MnSOD and Cu/ZnSOD induction and hence increased ROS production. Partial defects in respiratory complex I are associated with induction of the mitochondrial MnSOD, suggesting increased oxygen radical production (689).

Vascular blood flow is regulated by the contraction and dilation of the vascular smooth muscle cells, which in turn is regulated by diffusible effectors synthesized and released by the vascular endothelial cells, specifically, the vasodilator NO. NO is rapidly inactivated by superoxide anion ( $O_2^{\cdot-}$ ) and other ROS (690,691). The increased production of ROS should deplete the NO, causing loss of vasodilatory activity. The resulting vasoconstriction could in some instances be sufficient to block blood flow and cause a stroke. Later fluctuations in superoxide production would permit increased NO production and vasodilation, partially restoring blood flow.

After stroke-like episodes, the most common clinical presentation of the MTTL1\*MELAS3243G mutation is ophthalmoplegia, ptosis, and MM. CPEO is also the most common presentation of mtDNA rearrangement syndromes. Since every pathogenic rearrangement that has been studied to date alters or removes one or more tRNA genes (281), mtDNA rearrangement mutations also cause protein synthesis defects. Hence, ophthalmoplegia, ptosis, and MM are common presentations of severe defects in mitochondrial energy production.

Beyond the classical mitochondrial encephalomyopathy phenotypes of LS, MERRF syndrome, and MELAS syndrome, mtDNA protein synthesis mutations have been reported to produce an array of complex phenotypes. These range from a combination of MERRF, MELAS, and progressive encephalopathy symptoms, to ataxia, myoclonus and deafness, to gastrointestinal reflex and sudden infant death syndrome, to Rett syndrome (RS). All of these cases are the result of tRNA mutations except the RS case, which was associated with a 16S rRNA mutation (C2835T) (see Table 11-3 Panels A and B).

One example of this more severe class of mitochondrial encephalomyopathies in the MTTL1\*PEM3271delT mutation is associated with progressive encephalomyopathy (692). This mutation deleted one of the three Ts in the anticodon stem of the tRNA<sup>Leu(UUR)</sup>. The patient harboring the MTTL1\*PEM3271delT initially manifest at 5 years of age with progressive hearing loss leading to deafness by age 18 years. Seizures occurred in childhood, and the disease progressed into young adulthood to include MM (RRFs), retinitis pigmentosa, glaucoma, hypogonadism, dementia, and severe cerebral calcifications (Fahr disease). The patient died at 28 years of tonic-clonic seizures, renal failure, and sepsis. The percentage

of mutant mtDNAs was about 75% in the patient's skeletal muscle, but the mutant was absent in the mother's peripheral blood. Hence, this appears to be a new mutation that arose in the female germline and segregated sufficiently rapidly to give a lethal phenotype.

The more deleterious mtDNA tRNA mutations result in more severe central nervous system defects. These mutations can be so severe that individuals with moderately high percentages of heteroplasmic mutations fail to survive and reproduce. Hence, these are often "spontaneous" cases.

### 11.1.33 Mitochondrial Myopathy

The milder tRNA mutations can present with isolated MM, MM plus CPEO, or MM in association with Kearns-Sayre syndrome (KSS). This class of disease is occasionally referred to as "mitochondrial cytopathy" (see Table 11-3 Panels A and B). To date, more than 45 tRNA mutations have been reported with MM, CPEO, KSS, and mitochondrial cytopathy (see [www.mitomap.org](http://www.mitomap.org)).

Some examples of patients with MM due to a tRNA<sup>Leu(UUR)</sup> mutation are given by the MTTL1\*MM3250C and MTTL1\*MM3302G mutations. The MTTL1\*MM3250C mutation converts a weakly conserved T to a C. This mutation was associated with fatigability and RRFs, with one individual having respiratory muscle weakness and elevated lactate with exercise. The mutation was heteroplasmic, and varying percentages of mutant mtDNAs in skeletal muscle were associated with complex I and IV defects (693). The MTTL1\*MM3302G mutation was heteroplasmic and changed the highly conserved penultimate 3' A to a G. This mutation has been reported in two independent families. The first individual exhibited a progressive muscle weakness as a young adult (694), while the second exhibited an early-onset and rapidly progressive weakness and degeneration of the scapular flexor and extensor muscles resulting in a striking inability to hold the head erect against any lateral pressure (695). Both mutations were heteroplasmic and associated with skeletal muscle RRFs and OXPHOS enzyme defects. However, analysis of mitochondrial protein synthesis in lymphoblast and fibroblast cell lines failed to reveal a mitochondrial protein synthesis defect. Analysis of tRNA<sup>Leu(UUR)</sup> processing by monitoring the RNA 19 (16S rRNA + tRNA<sup>Leu(UUR)</sup> + ND1), 16S rRNA, tRNA<sup>Leu(UUR)</sup>, and ND1 transcripts led to the proposal that this mutation causes a defect in the processing of tRNA<sup>Leu(UUR)</sup> in the skeletal muscle, but not in lymphocytes and fibroblasts, presumably due to a tissue-specific tRNA processing enzyme (694). Additional studies are required to substantiate this hypothesis, but, if true, it provides a novel mechanism for tissue-specific defects in mutations changing highly conserved nucleotides.

An example of an mtDNA protein synthesis mutation in a different tRNA, tRNA<sup>Pro</sup>, is the MTTP\*MM15990A mutation. This mutation converted the proline anticodon UGG (codon CCA) to a serine anticodon UGA (codon UCA), rendering the mutant tRNA nonfunctional. This mutation caused classical MM without extraocular muscle involvement in a 7-year-old patient harboring 85% muscle mutant mtDNA in skeletal muscle. The mutation only affected mitochondrial protein synthesis of cultured cells when present in greater than 90% of the mtDNAs (696,697).

MM together with CPEO can be caused by mtDNA tRNA mutations, mtDNA rearrangement mutations, and nDNA replication enzyme mutations. In a survey of 28 KSS and 109 progressive external ophthalmoplegia (PEO) patients, 28 KSS patients had deletions and 1 harbored the MTTL1\*MELAS3243G mutation, while of the PEO patients, 46 (42%) harbored mtDNA deletions and 15 (14%) harbored the MTTL1\*MELAS3243G mutation. One additional PEO patient had the MTTK\*MERRF8344G mutation. KSS and CPEO patients who harbor mtDNA tRNA mutations are generally members of larger maternal pedigrees with several variously affected family members (678). Among the mtDNA protein synthesis mutations that cause CPEO, by far the most common is the MTTL1\*MELAS3243G mutation. Therefore, about half of the CPEO cases are due to mtDNA rearrangements and half due to mtDNA protein synthesis mutations. Of the those that result from point mutations, the majority of the cases are due to the MTTL1\*MELAS3243G mutation (660,669,677,698,699). Mutations in six other mtDNA tRNA genes have also been reported to cause CPEO.

Two additional tRNA<sup>Leu(UUR)</sup> mutations that have been associated with CPEO and KSS include the np T3273C (700) and G3249A mutations (701).

Ophthalmoplegia is also a major clinical feature of the tRNA<sup>Glu</sup> mutation at MTTG\*CIPOA10006G (702), and the tRNA<sup>Ser(AGY)</sup> mutation at MTTs2\*CIPO12246G (702). Ophthalmoplegia is also an occasional symptom for a variety of other deleterious mtDNA tRNA mutations, including the MTTK\*MERRF8344G mutation (678) and potentially others of the tRNA<sup>Leu(UUR)</sup> MELAS mutations (660). As is the case for mtDNA rearrangement mutations, milder renditions of the CPEO mutations can also cause diabetes mellitus and deafness. This phenotype is a common presentation of patients harboring 5–30% of the MTTL1\*MELAS3243G mutation (660,703).

The clear demonstration that both the MELAS and MERRF tRNA mutations inhibit mitochondrial protein synthesis indicates that this is the underlying mechanism that causes ophthalmoplegia, ptosis, and MM. This would also explain the origin of the symptoms in the CPEO and KSS patients with mtDNA rearrangements, since every pathogenic rearrangement that has been studied to date alters or removes one or more tRNA genes (704). Hence,

the rearrangement mutations would also cause protein synthesis defects, a result confirmed by cybrid studies of CPEO patient deletion cell lines. Hence, ophthalmoplegia, ptosis, and MM must result from primary defects in mitochondrial protein synthesis. Since mtDNA encodes seven subunits of complex I and three complex IV subunits, these would be the OXPHOS enzymes likely to be most affected, as has been observed. Hence, ophthalmoplegia, ptosis, and MM probably reflect severe defects in mitochondrial energy production.

Intestinal dysmotility is a common symptom of patients with mitochondrial encephalomyopathies and myopathies due to tRNA mutations. In some cases, this can be the presenting clinical concern. Five tRNA mutations have been reported in which gastrointestinal problems were the primary complaint. They occurred in tRNA<sup>Phe</sup> A608G, tRNA<sup>Trp</sup> G5532A, tRNA<sup>Lys</sup> G8313A, tRNA<sup>Gly</sup> A10006G, and tRNA<sup>Ser(AGY)</sup> C12246G (see Table 11-3 Panels A and B). However, the stereotypical presentation of intestinal dysmotility is most commonly seen in the autosomal recessive mitochondrial disease, mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), resulting from mutations in the thymidine phosphorylase (TP) gene. MNGIE has been reported in association with a tRNA<sup>Lys</sup> G8313A mutation (705).

### 11.1.34 Cardiomyopathy

Cardiomyopathy is also a common clinical manifestation of mtDNA protein synthesis mutations, frequently found in association with MM. Eight mtDNA tRNA mutations have been found to be associated with cardiomyopathy in association with myopathy. These involve tRNA<sup>Leu(UUR)</sup> A3260G and C3303T, tRNA<sup>Ile</sup> A4295G and A4300G, tRNA<sup>Lys</sup> A8348G, tRNA<sup>Gly</sup> T9997C, tRNA<sup>His</sup> G12192A, and tRNA<sup>Leu(CUN)</sup> T12297C (see Table 11-3 Panels A and B).

Examples of mtDNA protein synthesis mutations that manifest as cardiomyopathy with MM include the MTTL1\*MMC3303T and MTTL1\*MMC3260G mutations. The MTTL1\*MMC3303T mutation was found in two infants who died at 10 weeks and 9 months of age, and was observed to be heteroplasmic (706). The tRNA<sup>Leu(UUR)</sup> mutation MTTL1\*MMC3260G, associated with hypertrophic cardiomyopathy, was been reported in two independent pedigrees (707,708). Individuals harboring the MTTL1\*MMC3260G mutation manifest symptoms of congestive heart failure as young adults, ultimately leading to hypertrophy with disorganized cardiomyocytes, fibrosis, and cardiac conduction defects (Wolff–Parkinson–White syndrome). Other clinical manifestations in the maternal lineage included insulin-dependent diabetes mellitus (IDDM) and cataracts. This heteroplasmic mutation has been shown to segregate along the maternal lineage, and the percentage mutant mtDNAs has been shown to correlate with the level of skeletal muscle complex I deficiency, oxygen

consumption, and clinical severity (708). Transmitochondrial cybrids harboring the MTTL1\*MMC3260G mutation prepared from patient myoblasts have been found to have defective protein synthesis and mitochondrial respiration (709), confirming the pathogenicity of this mutation.

A heteroplasmic tRNA<sup>Gly</sup> mutation, MTTG\*MHCM 9997C, has been reported in associated with maternally transmitted hypertrophic cardiomyopathy in a single, multigeneration family. This mutation changes a highly conserved base, has not been observed in controls, and results in multiple OXPHOS enzyme defects (710).

A heteroplasmic tRNA<sup>Ile</sup> mutation has been associated with adult-onset hypertrophic cardiomyopathy with slow progression. This mutation, MTTI\*MICM4300G, was found in a maternally inherited pedigree in which three maternal relatives were diagnosed with hypertrophic cardiomyopathy and several other maternal relatives exhibited mild clinical and electrocardiographic indications of hypertrophic cardiomyopathy (711). Although RRFs were found in the patient's skeletal muscle, no OXPHOS biochemical defects were detected in cardiac or skeletal muscle.

Cardiomyopathy may also be seen in association with the classical MTTK\*MERRF8344G and MTTL1\*MELAS3243G mutations (660).

Finally, two mutations have been reported to cause fatal infantile cardiomyopathy plus (FICP), the plus including encephalopathy. In the first case, a tRNA<sup>Ile</sup> mutation, MTTI\*FICP4269G, was observed in an 18-year-old who died with hypertrophic cardiomyopathy, MM, renal disease, hearing loss, generalized seizures, and mental retardation. The mutation was heteroplasmic in the mother and proband, was associated with morphologic changes of the mitochondria in cultured cells, and resulted in a protein synthesis defect in cybrids derived from patient fibroblasts (712,713).

The second case of FICP, the MTTI\*FICP4317G mutation, was described in an infant who died at 1 year of severe hypertrophic cardiomyopathy together with skeletal muscle necrosis and a complex I and IV deficiency in the heart (714). While the mutation was proposed to alter the TΨC loop by creating a new G–C base pair, the mutation was not reported to be heteroplasmic, and only 28 controls were screened. Hence, the etiology of this mutation requires confirmation.

### 11.1.35 Deafness, Sensorineural Hearing Loss, and Aminoglycosides

Maternally inherited deafness and/or aminoglycoside-induced deafness has been associated with protein synthesis mutations, eight in the 12S rRNA mutations and five tRNA mutations, three in tRNA<sup>Ser(UCN)</sup>, one in tRNA<sup>His</sup>, and one in tRNA<sup>Glu</sup>. The mutations seen in the 12S rRNA are A827G, T961C, T961delTinsC, T961insC, T1005C, A1116G, C1494T, and A1555G. The three

tRNA<sup>Ser(UCN)</sup> mutations are at T7510C, T7511C, and 7472insC, the tRNA<sup>His</sup> mutation is at G12183A, and the tRNA<sup>Glu</sup> mutation is at T14709C (see Table 11-3 Panels A and B).

The MTRNR1\*DEAF1555G is the best characterized of the mtDNA deafness mutations. The MTRNR1\*DEAF1555G mutation, though consistently homoplasmic, has now been confirmed in multiple independent studies (683,715–718). Individuals harboring this mutation were first observed in a large Middle Eastern pedigree featuring sensorineural hearing loss along the maternal lineage. The maternal transmission with variable penetrance was hypothesized to be the combination of the maternally transmitted MTRNR1\*DEAF1555G mutation acting together with an autosomal recessive nuclear gene (715). Subsequent studies in China and elsewhere have shown that individuals harboring this mutation are acutely sensitive to aminoglycoside inhibition. The mutation occurs at the end of a stem-and-loop structure in the small rRNA subunit, adding a terminal base pair and thus making the mitochondrial ribosome more like a bacterial ribosome at the aminoglycoside binding site (716). Pedigrees harboring this mutation have occasionally been observed to manifest other neurologic signs, including the extrapyramidal signs of tremors and rigidity seen in PD (683). Despite the alteration of rRNA structure, a protein synthesis defect has not been reported for this mutation.

Confirmation that the MTRNR1\*DEAF1555G (nt 1555 A to G) mutation is a pathogenic mutation comes from patients harboring the nt 1494 C-to-T variants in the 12S rRNA gene (see Figure 11-6). The 1494C and 1555A bases are in apposition to each other in the 12S rRNA but do not form a base pair. However, if the C at nt 1494 is mutated to a T or the A at nt 1555 is mutated to a G, then a base pair is formed, extending the adjacent stem by one nucleotide and making the ribosome more bacteria-like (719). The nt 1494T and nt 1555G mutations are relatively innocuous by themselves, the nt 1494T variant having been observed in both a deaf patient (720) and a normal individual from haplogroup A (721). However, these variants greatly increase sensitivity to aminoglycoside antibiotic-induced deafness (716,718,720).

The two tRNA<sup>Ser(UCN)</sup> mutations associated with sensorineural hearing loss have been reported in adjacent nucleotides: T7510C (722) and T7511C (723). Both were heteroplasmic. By contrast, the tRNA<sup>His</sup> mutation at G12183A was homoplasmic (724). In addition to these tRNA mutations associated with deafness, two other tRNA mutations have been reported to be associated with deafness in addition to other clinical manifestations.

Maternally transmitted bilateral sensorineural hearing loss has also been observed associated with a homoplasmic tRNA<sup>Ser</sup> mutation, MTTS1\*DEAF7445G/

MTCO1\*DEAF7445G (725,726). This mutation was subsequently reported to be heteroplasmic within this family (727) and in another (728) (see Table 11-3). Since this mutation occurs in the final base of the COI termination codon and does not change the sense of the codon, it has been proposed that the 7445G mutation impairs the adjacent tRNA<sup>Ser</sup> (729).

### 11.1.36 Diabetes Mellitus with/without Deafness

The genetic linkage of mtDNA tRNA (730) and rearrangement (731,732) mutations to type 2 diabetes has directly implicated mitochondrial protein synthesis defects in the etiology of diabetes and the metabolic syndrome. Evidence that mtDNA defects are a common factor in the etiology of diabetes comes from the observation that, as the age of onset of the proband increases, the probability that the mother was the affected parent also increases, reaching a ratio of 3:1 for patients with a mean age of onset of 46 years (412). These observations have been linked to the larger human metabolic syndrome through the identification of an mtDNA tRNA<sup>Ile</sup> mutation at np T4291C that causes hypertension, hypercholesterolemia, and hypomagnesemia (renal ductal convoluted tubule defect). This mutation was found in a maternal pedigree in association with reduced mitochondrial ATP production and the secondary clinical findings of migraine, hearing loss, hypertrophic cardiomyopathy, and MM (733).

12S rRNA mutations (C1310T and A1438G) and six tRNA mutations (tRNA<sup>Leu(UUR)</sup> A3243G, T3264C, and T3271C; tRNA<sup>Ile</sup> T4291C; tRNA<sup>Lys</sup> A8296G; and tRNA<sup>Ser(AGY)</sup> C12258A) have been associated with diabetes and the metabolic syndrome. The most common mtDNA mutation associated with diabetes mellitus is the MTTL1\*MELAS3243G mutation (703,730,734,735). The MTTL1\*MELAS3243G mutation has been found at about 1.4% in IDDM and NIDDM patients (703). The frequency is higher for NIDDM if the mother is also affected (5.7%), and much higher if the patients have both NIDDM and sensorineural hearing loss, being 60% (3 of 5) in a Japanese study (736) and 10% (2 of 20) in a British study (737). While the great majority of diabetes mellitus MTTL1\*MELAS3243G patients have a primarily NIDDM presentation, many either present with or progress to IDDM (703,736). Furthermore, slowly progressive IDDM has been associated with the MTTL1\*MELAS3243G mutation, and in one study of islet-cell antibody-positive patients with progressive NIDDM, the MTTL1\*MELAS3243G mutation was found in 3 of 27 of the patients (11%), suggesting that islet cell loss and subsequent autoantibody production can also be associated with mitochondrial defects (738,739). These and other observations have led to a delineation of the characteristics of MTTL1\*MELAS3243G diabetes mellitus, which

include maternal transmission; variable clinical phenotype, including NIDDM, slowly progressive IDDM, and IDDM; young to middle-age onset; tendency toward progression; and association with sensorineural hearing loss. Moreover, many of these patients are lean and require insulin, but are less prone to ketoacidosis. They show a delayed insulin response to glucose and impaired glucagon secretion, and they may or may not have autoantibodies to pancreatic islet cells (703,736,740). The MTTL1\*MELAS3243G mutation is invariably heteroplasmic in diabetes mellitus patients, and generally present as a lower percentage mutant than commonly found in MELAS patients, frequently in the range of 5–30% in blood, with levels potentially higher in muscle and fibroblasts (734,735). Indeed, it is not uncommon that blood cells will lack the mutation even though it is present in post-mitotic tissues. Hence, this cause of diabetes mellitus is probably underdiagnosed.

Due to the systemic nature of the MTTL1\*MELAS3243G mutation, it is not uncommon for patients presenting with diabetes mellitus to also exhibit additional clinical manifestations. Examples include diabetes mellitus with diabetic amyotrophy (734), diabetes mellitus with diarrhea and abdominal pain involving 37% mutant mtDNAs in blood and 70% mutant mtDNAs in gastric and rectal mucosa and skeletal muscle (741), and diabetes mellitus with post-insulin treatment neuropathy (742).

In addition, the common tRNA<sup>Lys</sup> MTTK\*MERRF 8344G mutation has been identified in one three-generation pedigree that presented with diabetes mellitus and deafness and harbored the MTTK\*MERRF 8344G mutation, with mutant mtDNA levels ranging from 12% to 28% in peripheral blood cells (640). However, this MERRF mutation is not a common cause of diabetes mellitus since the mutation was not found in a survey of several hundred Japanese diabetes mellitus patients (736).

The MTTT1\*DMDF7472Cins has been found in a maternally inherited pedigree featuring progressive, bilateral hearing loss as the most common clinical manifestation. Ataxia due to cerebellar dysfunction and myoclonus were also prominent in the family (743). This mutation involves the insertion of a C within a homopolymeric stretch of 6 C nucleotides, was found to be heteroplasmic in the family, was not found in nearly 400 controls, resulted a complex I biochemical deficiency, and likely alters the conformation of the TΨC stem-loop. Cybrid studies confirmed the pathogenicity of this mutation, and there was a correlation between proportion of mutant mtDNA and clinical manifestations in blood (743).

Myopathy with diabetes mellitus has been associated with a heteroplasmic MTTE\*MDM14709G mutation in two families (744,745) one of which also presented with mental retardation and cerebellar ataxia (744). Histologic and/or immunohistochemical analysis of patient

skeletal muscle revealed the classical signs of myopathy: RRFs, COX-negative fibers, abnormal mitochondrial morphology, and paracrystalline inclusions. Biochemically, this tRNA<sup>Glu</sup> mutation caused a reduction in complex I and IV specific activities and, in myoblasts, resulted in a mitochondrial protein synthesis defect (744).

Diabetes mellitus is also seen in Wolfram syndrome, which is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness. Other less common endocrine and neurologic symptoms include hypogonadism, atonic bladder, ataxia, insomnia, seizures, and psychiatric disorders (703). One patient diagnosed with Wolfram syndrome including diabetes mellitus, optic atrophy, and sensorineural deafness was found to harbor the MTND4\*LHON11778A mutation (514), and another case of Wolfram syndrome was found to contain a 7.6-kbp mtDNA deletion (746). However, sequence analysis of the blood cell tRNAs from two other Wolfram patients failed to reveal any disease-specific mutations (682). Hence, the role of mtDNA protein synthesis mutations in Wolfram syndrome remains unclear (703).

### 11.1.37 Movement Disorders and Dementias

In certain instances, mtDNA mutations can present with neuropsychiatric symptoms including depression, movement disorders, and dementias. Movement disorders have been most commonly associated with mtDNA polypeptide gene mutations. Examples discussed previously include the MTND6\*LDYT14459A mutations (537,538), which can present as generalized dystonia, and the report of the MTND4\*LHON11778A mutation associated with Parkinson-like symptoms (518,523). A tRNA<sup>Val</sup> T1659C mutation has also been linked to movement disorders (747).

Patients harboring mtDNA mutations may also develop progressive dementia. One patient with progressive cognitive decline, dementia, deafness, ataxia, and chorea was found to be heteroplasmic for a tRNA<sup>Trp</sup> mutation, MTTW\*DEMCHO5549A. Post-mortem analysis of the brain revealed diffuse and moderate neuronal loss in the cortex and basal ganglia, with gliosis present throughout the brain. RRFs and COX-negative-staining fibers were evident on skeletal muscle analysis, as were morphologically abnormal mitochondria on electron microscopy of skeletal muscle. A complex I defect was detected in mitochondrial respiration assays. Hence, this tRNA<sup>Trp</sup> mutation demonstrates that respiratory defects can cause dementia (748). This has been substantiated by the identification of the tRNA<sup>Gln</sup> gene mutation at np 4336, MTTQ\*ADPD4336G, which has been associated with about 5% of late-onset AD and also linked to hearing loss and migraine (633,749–751). The tRNA<sup>Gln</sup> 4336C mutation has also been associated with a 16S rRNA mutation at G3196A (633).

### 11.1.38 Diseases Resulting from Rearrangement Mutations

A rearrangement mutation is defined in this chapter as a mutation encompassing two or more genes. These can be insertions, deletions, or a combination of the two. Since most of the mtDNA genes are punctuated by tRNAs, rearrangement mutations generally affect one or more tRNAs (752). Therefore, most rearrangement mutations perturb mitochondrial protein synthesis. As a result, patients harboring mtDNA rearrangements frequently have arrays of clinical phenotypes similar to those seen in patients with point mutations in individual tRNA or rRNA genes. Accordingly, the most common rearrangement phenotypes are diabetes, CPEO, and KSS. In addition, mtDNA deletions also cause the more severe Pearson marrow-pancreas syndrome.

#### 11.1.38.1 Diabetes Mellitus with/without Deafness.

As with MTTL1\*MELAS3243G mutations, which can cause CPEO but also diabetes mellitus (703,730,734,735), mtDNA rearrangement mutations can also manifest as diabetes mellitus and deafness (731,732).

Rearrangements in mtDNA have repeatedly been associated with diabetes mellitus. This association was first clearly demonstrated for KSS patients with mtDNA duplications. The smaller the duplication, and larger the reciprocal deletion, the more likely the patient is to develop diabetes mellitus (753–757).

The first proof that type 2 diabetes mellitus could be caused by an mtDNA insertion–deletion mutation came from the study of a large African American pedigree that showed maternal inheritance of diabetes and deafness and harbored an mtDNA duplication and reciprocal deletion (731,732). Since that observation, diabetes mellitus has been found to be a common clinical manifestation in patients with mtDNA duplications, generally in association with KSS (757,758).

In the initial African American family with type 2 diabetes mellitus and sensorineural hearing loss, the maternal relatives developed hearing loss in their 20s and 30s and type 2 diabetes mellitus in their 30s and 40s. Occasional individuals in the rearrangement pedigree experienced stroke-like episodes associated with cortical and brain stem lucencies on MRI examination. None of the patients had ophthalmoplegia or ptosis, nor did they have MM as detected by muscle histology. However, detailed biochemical analysis of several family members revealed a generalized OXPHOS defect in the skeletal muscle. Physiologic analysis indicated that all maternal relatives developed IDDM, with some individuals developing diabetic ketoacidosis. Glucose tolerance tests revealed that severely affected individuals were unable to respond to hyperglycemia with increased insulin production from beta cells or decreased glycogen production from alpha cells (731).

The mtDNA rearrangement in this maternally inherited pedigree consisted of three main types of mtDNA molecules: (1) normal mtDNAs; (2) duplicated mtDNAs

containing an insertion of 6.1 kbp of the mtDNA encompassing from np 4389 in the tRNA<sup>Gln</sup> gene to np 14822 in the *MTCYB* gene and including the ND1, 16S rRNA, 12S rRNA, and part of the *MTCYB* genes, as well as the tRNA<sup>Ile</sup>, tRNA<sup>Leu(UUR)</sup>, tRNA<sup>Val</sup>, tRNA<sup>Phe</sup>, tRNA<sup>Pro</sup>, and tRNA<sup>Thr</sup> genes, and the D-loop including O<sub>H</sub>; and (3) finally, deleted mtDNAs that lack 10.4 kbp of mtDNA, including 11 of the 13 OXPHOS genes, 15 of 22 tRNAs, O<sub>L</sub>, and 75 bp of the 5' end of the *MTCYB* gene. The deleted molecules appear to be present as a dimer of about 12 kbp, and the rearrangement is encompassed by a 10-bp direct repeat (5'-CACCCCATCC-3'). Lymphoblastoid cell lines carrying this rearrangement exhibit a partial protein synthesis defect. Extended propagation results in selective enrichment for the duplicated molecules and loss of the deleted and normal mtDNAs. Moreover, white blood cells from patients have an excess of duplicated molecules, while the post-mitotic muscle had a higher proportion of deleted than duplicated mtDNAs. These results suggest that the duplicated molecules with the extra O<sub>H</sub> are preferentially replicated and hence transmitted through the germline, and that the deleted molecules are generated from the duplicated molecules through a recombinational process in post-mitotic tissues. While the deleted molecules have only one origin, O<sub>H</sub>, it is possible that they could also replicate. If the two components of the dimers were arrayed in a head-to-tail position, then there would be an O<sub>H</sub> for each strand (731,732).

This pedigree is remarkable in that it harbored the same type of duplication and deletion dimer molecular defect that has been documented for diabetes mellitus in association with KSS patients and Pearson syndrome patients who progress to KSS (754,756–759), yet none of the patients exhibited evidence of ptosis, ophthalmoplegia, or MM.

A second family has been reported also with a maternally inherited type 2 diabetes in association with an mtDNA duplication (760).

In another family, a patient was described with dystonia, external ophthalmoplegia, slowly progressive proximal muscle weakness, no RRFs on muscle biopsy (though showing mitochondrial hyperplasia), and diabetes mellitus that developed at age 36 and was treated with insulin. This individual also contained normal and duplicated mtDNAs, with the duplication encompassing nucleotides 13,445 through 3318 and flanked by imperfect direct repeats at nps 3318 through 3337 and 13,445 through 13,462. This duplication duplicated the 12S and 16S rRNAs, ND6 and *MTCYB* genes, O<sub>H</sub>, and the encompassed tRNAs, and was found in 15% of the proband's muscle mtDNA, 80% of his blood mtDNA, and 40% of his mother's blood mtDNA (753). In a second family, the child presented at 8 years with diabetes mellitus and occasional episodes of ketoacidosis, which progressed on to CPEO and MM, with the individual dying at age 20 of cardiac dysrhythmia. The patient harbored a family of mtDNA molecules, including normal, duplicated, deleted, and deletion dimers that

were widely distributed among her tissues, including her pancreas (757). Thus, these two families have duplications similar to those of the maternally inherited diabetes mellitus and deafness family and also had diabetes without or without RRFs, but the patients did have ophthalmoplegia. This implies that mtDNA rearrangement syndromes represent a phenotypic continuum with isolated diabetes mellitus and deafness being the mildest presentation, CPEO and KSS intermediate, and Pearson marrow–pancreas syndrome the most severe.

While diabetes mellitus and deafness can result both from insertion–deletion rearrangements and from the MTLL1\**MELAS*3243G mutation, the phenotypes of the mtDNA rearrangements and the MTLL1\**MELAS*3243G mutations may be somewhat different in that the rearrangement patients are more frequently insulin-requiring diabetics (731,732,757). In one case this has been associated with the loss of pancreatic beta cells (757).

Because of the clinical variability of the mtDNA rearrangement syndromes, diabetes mellitus together with mtDNA rearrangements can be associated with a spectrum of other clinical symptoms. A 5-kbp deletion has been identified in an infant with diabetic ketoacidosis, rickets, and de Toni–Debre–Fanconi syndrome (761), and a 5778-np deletion was detected by PCR in patients with diabetic amyotrophy, diabetic myoatrophy and nephropathy, and diabetic fatty liver, though this deletion was not confirmed by Southern blot and the same deletion was found at lower levels in controls (762). Finally, one patient has been reported with Wolfram syndrome including early-onset diabetes mellitus, optic atrophy, and deafness in association with a 7.6-kbp mtDNA deletion (746), though analysis of another Wolfram patient failed to reveal an mtDNA defect (763).

**11.1.38.2 Ophthalmoplegia, Ptosis, and Mitochondrial Myopathy.** Ophthalmoplegia and ptosis are common manifestations of mtDNA rearrangement syndromes. Patients with ophthalmoplegia, ptosis, and MM resulting from mtDNA rearrangements can have a wide range of additional symptoms. Patients with milder disorders may present with only ophthalmoplegia, ptosis, and MM, with an age of onset ranging from the late 20s up to late adulthood and a relatively mild course. Such patients are designated as having CPEO. By contrast, other patients can present with ophthalmoplegia, ptosis, and MM prior to age 20 and experience multiple additional symptoms, including retinitis pigmentosa and at least one of the following: cardiac conduction defects, cerebellar ataxia, or elevated cerebrospinal fluid protein (>100 mg/dL) (758,764). These patients are said to have KSS. Other symptoms that may be observed in KSS or CPEO patients can include optic atrophy, hearing loss, seizures, dementia, cardiomyopathy, cardiac dysrhythmias, renal failure, endocrine disorders including diabetes mellitus, respiratory failure, lactic acidosis (259,765), chronic diarrhea, and villous atrophy in early childhood (766).

Approximately 83% of KSS and 47% of CPEO patients are the product of mtDNA rearrangements (752). The great majority of these cases are new spontaneous mutations derived from a single clonal event such that all of the affected tissues of the patient are heteroplasmic for normal mtDNAs plus rearranged mtDNAs with a single unique breakpoint junction. Presumably, most of these mutations arose in the oocyte or early in development. A few cases, however, involve rearrangements that can also be detected at low levels in the mother and/or other maternal relatives (767).

Most of the remaining cases are the results of various mtDNA tRNA point mutations, including the tRNA mutation MTTL1\*MELAS3243G (326,660,698,699) (see Table 11-3 Panels A and B). A small percentage of patients with PEO harbor multiple mtDNA rearrangements caused by the inheritance of an autosomal dominant or recessive nuclear mutation that predisposes the mtDNAs to rearrangements (768).

mtDNA rearrangements associated with CPEO and KSS can include deletions, insertions, or a combination of the two (356). The first mtDNA rearrangements were recognized in skeletal muscle of patients with MM (7). Subsequent analysis of a large number of patients revealed that mtDNA rearrangements could be associated with four interrelated phenotypes: KSS, CPEO, Pearson marrow-pancreas syndrome, and maternally inherited diabetes mellitus and deafness.

In addition to ophthalmoplegia and ptosis, patients with CPEO and KSS due to mtDNA rearrangements have a progressive severe MM (see Figure 11-10). Additional histologic analysis of CPEO and KSS muscle has revealed bands of COX-deficient (COX<sup>-</sup>) and SDH-hyperreactive (SDH<sup>+</sup>) activity along the muscle fibers. These COX<sup>-</sup> and SDH<sup>+</sup> fibers generally correspond to regions of mitochondrial proliferation and RRFs, high levels of mutant mtDNA, and induction of nDNA and mtDNA OXPHOS gene expression (216,217,769-771).

The great majority of KSS and CPEO cases are due to spontaneous mtDNA rearrangements (281,699). About 80% of the rearrangement breakpoints are flanked by direct repeats of 4–16 nucleotides, 7% involve direct repeats of 4–6 nucleotides, and 12% do not involve a direct repeat (281). Hence, the majority of rearrangements involve a region of homology, suggesting some type of sequence-associated rearrangement mechanism. Many KSS patients harbor an interrelated family of rearranged molecules, all of which share a common breakpoint junction. These frequently include, in addition to normal mtDNAs, a duplicated mtDNA, a deletion monomer that retains only the duplicated region, and a deletion dimer containing two copies of the inserted sequence (758,759).

Duplications may predispose individuals to the more severe disease, since in one survey, 10 of 10 KSS patients were found to have duplications as well as deletions, while 8 of 8 CPEO patients harbored only deletion

monomers (756). Furthermore, the amount of the duplicated molecule in the KSS patients appeared to correlate with the duplication size: The larger the duplication, the lower the level of duplicated molecules. Moreover, the patients with the smallest duplications (largest deletions) also had deletion dimers. In skeletal muscle, as the disease progresses, the normal and duplicated mtDNAs decline while the deletion dimers increase, and the patients harboring duplications are more likely to develop diabetes mellitus than those with only deletions (758). These observations have led to the speculation that duplicated molecules are propagated more readily than deleted molecules and thus are more widely distributed among the tissues. Hence, patients harboring duplications have more organ systems affected and thus more severe disease (758,772).

While a wide variety of rearrangement breakpoints have been mapped, the great majority of deletions tend to fall into two areas defined by the O<sub>H</sub> and O<sub>L</sub> origins of replication (8). Moreover, deletions are not uniformly distributed. Approximately one-third to one-half of all deletion events occur at the common deletion breakpoint between nps 8469:13,447 joining the mtDNA genes *MTND5* and *MTATP8*, and removing 4977 nps. This “common” 5-kbp deletion occurs between two 13-base pair direct repeats at 8470 through 8482 and 13,447 through 13,459, one repeat of which is lost and the other retained (773–775). Two other frequently observed rearrangements bring together nps 7841 and 13,905 in the *MTCO2* and *MTND5* genes, removing 6063 nps at a 6- to 8-base pair direct repeat; and occur between nps 8648:16,085 in genes *MTATP6* and *MTTP*, removing 7436 nps at a 12-base pair direct repeat (281). The increased frequency of deletions at these breakpoints suggests a predominant rearrangement mechanism. In the case of the common 4977-np deletion, the break occurred in one nucleotide outside the direct repeat. This permitted a demonstration that the upstream 13,447 through 13,459 repeat was retained while the downstream 8470 through 8482 repeat was lost. Since this corresponds to the direction of H-strand replication, it has been proposed that one mechanism for mtDNA rearrangement was slip-mispairing. As replication proceeds, a new H-strand is synthesized along the L-strand template starting from O<sub>H</sub> and moving down in nucleotide numbers from position 16,569, with the parental H-strand being displaced as a single-stranded loop. Direct repeats in the parental H-strand are thus exposed and can base pair with downstream homologous repeats exposed on the L-strand by the replicating fork. Breakage of the single-stranded H-strand on the downstream side of the base-paired repeat would create a 3'-OH, which would permit re-initiation of replication continuing along the template, beginning downstream of the L-strand repeat and skipping the intervening mtDNA (775,776).

Slip-mispairing has been confirmed as an important mutational mechanism in mtDNA through studies of a spontaneous mtDNA mutation that occurs in the D-loop

of a specific European haplogroup I mtDNA lineage. Haplogroup I is defined by the novel restriction site polymorphisms *Hae*II site loss at np 4529, *Ava*II site gain at position 8249, *Alu*I site gain at 10028, and *Bam*HI site gain at 16389 (777). Individuals who harbor this mtDNA haplotype are prone to develop a heteroplasmic 270-np duplication in the D-loop between np 302 and np 567. This tandem duplication duplicates P<sub>H</sub> (nps 545 through 567), P<sub>L</sub> (nps 392 through 445), CSBIII (nps 346 through 363), and part of CSBII (nps 299 through 315) (777,778). While the original report proposed that this duplication predisposed mtDNAs to subsequent large-scale deletions (778), this has not been confirmed (758,777,779). Subsequent analysis revealed that haplogroup I mtDNAs harbored a germline mutation that inserted a run of C nucleotides at nps 568 through 573. This created a tandem repeat of the sequence 5'-ACCCCCCCC=CCCC-3' on each side of duplicated region. Every individual harboring this germline mutation was found to be heteroplasmic for the duplication in all somatic tissues tested. Since the duplicated regions are tandemly arrayed, the simplest explanation for this self-generating D-loop duplication is slip-mispairing (777). While predisposition to this duplication does not appear to be pathogenic per se, it has been found to be present at relatively high levels (32%) in one patient with MM including RRFs and partial COX deficiency. This patient also had a small percentage of mtDNAs with this region triplicated (779). This observation could suggest that either the duplication can be toxic at high levels or, alternatively, that the duplicated mtDNA is preferentially amplified in MM due to the presence of the additional promoters and O<sub>H</sub>.

Alternative deletion mechanisms that have been proposed include topoisomerase II cleavage (776) and homologous recombination. Putative topoisomerase II recognition sequences have been observed in the vicinity of certain mtDNA deletions and proposed to play a role in removal of sequences (780,781). Recombination is likely to play an important role since it is now established that many rearrangement patients harbor a complex array of related molecules, including duplication molecules, deletion monomers, and deletion dimers, suggesting that they may be interconverted by a recombinational process (356,756,759). mtDNA recombination has now been confirmed in mice harboring two mtDNAs that differ by 91 nucleotides (782) and has been reported in somatic cell hybrids between two cell lines harboring non-overlapping CPEO deletions, both of which retained OH and OL. In the hybrids, the mtDNAs complemented each other to give respiratory competence, and a few cell lines have been found to contain recombinant molecules involving the coalescence of the two deleted molecules (783). Hence, mtDNA recombination does occur in cultured human cells, though in this experiment its frequency was very low.

The pathophysiology of KSS and CPEO resulting from spontaneous mtDNA rearrangements appears to be the result of a protein synthesis defect combined with the

stochastic distribution of the mutant molecules during development. All KSS- and CPEO-associated deletions studied to date remove at least one structural RNA (tRNA or rRNA) essential for mitochondrial protein synthesis. Cytoplasmic transfer of deleted molecules from patient cells to  $\rho^0$  HeLa cells confirmed that the deleted molecules caused a defect in mitochondrial protein synthesis. In cybrids with up to 60% deleted mtDNAs, the normal mtDNAs complemented in *trans* permitting high respiration and synthesis of the mtDNA-encoded polypeptides. However, above the 60% mutant mtDNA threshold, mitochondrial respiration, protein synthesis, and the level of the individual mitochondrial polypeptides declined precipitously, ultimately falling to zero (784). This threshold effect on protein synthesis for deletion mutations explains why KSS and CPEO, like the pathogenic tRNA mutations, are frequently associated with MM and RRFs. Analysis of the tissue distribution of mtDNA deletions in KSS and CPEO patients at autopsy has revealed that the rearranged molecules are broadly distributed throughout the tissues of the body (757,772,785). The interesting exception is blood, which is commonly devoid of the mtDNA deletions (7,757,772,775), though duplications have been found (758). Hence, molecular diagnosis of KSS and CPEO generally requires a muscle biopsy.

The time in development when pathogenic mtDNA deletions arise is not yet known. However, their broad tissue distribution would imply a mutation in the oocyte or very early in development. This is supported by surveys of the mtDNAs of human oocytes left over from in vitro fertilization clinics, which have revealed that many oocytes do harbor deletions. Eight of the 15 oocytes harbored the common 4977-np deletion, confirming that deletions must occur early in development (786,787). The maximum number of molecules containing the 5-kbp deletion was 171 molecules, or about 0.1% (786). Moreover, a survey of oocytes from women of different ages revealed that, of women less than 38 years, 28% of the oocytes had the common deletion, while for women older than 38, 93% of the oocytes had this deletion. Consequently, the mean age of women without oocyte deletions was 31.4 years, while that of women with deletions was 37.7 years (787). This correlates with a marked increase in ovarian mtDNA deletions at menopause, about age 45 (788). Thus, it appears that mtDNA rearrangements may arise in the oocyte or early in development, and the frequency of mtDNA rearrangement syndromes may increase with maternal age at conception.

Molecular histologic analysis of the distribution of deleted mtDNAs in skeletal muscle of KSS and CPEO patients has revealed that the levels of mtDNA deletions increase with age (758,789,790), and that the deleted molecules are not uniformly distributed along the length of the muscle fiber. Staining muscle fibers for COX and SDH have revealed that the COX levels vary from normal to absent and that the SDH staining is normal where COX

is normal, but greatly increased in COX-negative regions (467). In situ hybridization and regional PCR amplification have shown that regions that are COX negative have increased levels of the deleted mtDNAs and a coordinate induction of mtDNA transcripts from the undeleted genes. By contrast, the COX-positive regions have predominantly normal mtDNAs (770,771,791). These observations imply that the deleted mtDNAs are initially scattered along the muscle fiber, but that, as the individual ages, there is a selective amplification of the deleted molecules, ultimately reaching a high enough concentration to inhibit mitochondrial protein synthesis and cause COX deficiency.

The mechanism by which the deleted mtDNAs are selectively amplified remains unknown, though two hypotheses have been put forward. The first hypothesis is that the deleted molecules are shorter and thus have a replicative advantage (8). Mitochondrial proteins and mtDNAs are known to be continuously, albeit slowly, turned over in post-mitotic tissues (792–795). Hence repeated replication cycles might favor shorter deleted mtDNAs or duplicated molecules with extra origins. The alternative hypothesis is that the nuclei adjacent to mutant mtDNAs and mitochondria sense the OXPHOS defect of the mutant mitochondria and attempt to compensate by inducing mtDNA replication and mitochondrial biogenesis in the surrounding mitochondria. Coordinate induction of nuclear and mtDNA OXPHOS gene expression has been documented in skeletal muscle of patients with both mtDNA rearrangement and tRNA mutations (216,217,769), and since skeletal muscles are syncytia, each nucleus controls a particular cytosolic domain (796). If mtDNA OXPHOS gene expression is modulated by a mitochondrial substrate, such as NADH, then inhibition of the ETC by an mtDNA mutation would cause a local rise in NADH and concomitant increase in mitochondrial gene expression in the adjacent nucleus. Such a process could be mediated via a nuclear transcription factor that activates OXPHOS gene expression. The factor has been identified binding to the REBOX sequence element located in a variety of nuclear bioenergetic genes and possibly also in the D-loop of mtDNA. The binding of the REBOX binding factor is stimulated by a reducing environment (192,206). Thus, in cells with partial respiratory deficiency, increased NADH could activate REBOX binding factor to bind to the REBOX element and thus stimulate the nucleus to induce the biogenesis of the surrounding mitochondria, including the associated mutant mtDNA. The resulting increase in number of mutant mtDNAs would further increase NADH and stimulate nuclear gene expression, creating a self-perpetuating feedback loop that would preferentially amplify the mutant mtDNAs (493,797). Whatever the mechanism, it would appear that it is the regional bioenergetic defect caused by the selective amplification of the mutant mtDNAs that causes the progressive decline in muscle function in KSS and CPEO.

**11.1.38.3 Pearson Marrow–Pancreas Syndrome.** A more severe form of the CPEO-KSS mtDNA rearrangement syndrome presents in the first 5 years of life with pancytopenia (loss of all blood cells). This condition is known as the Pearson marrow–pancreas syndrome. Pearson patients develop a severe transfusion-dependent, macrocytic anemia with varying degrees of neutropenia and thrombocytopenia. The bone marrow of Pearson patients shows extensive vacuolization of erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. Pearson patients generally die due to complications of the bone marrow dysfunction or transfusions. In addition to pancytopenia, many Pearson patients develop exocrine pancreatic insufficiency, hepatic failure, renal failure, and other neuromuscular problems (259,798–802). Analysis of circulating white blood cells has revealed a generalized respiratory defect in association with mtDNA rearrangements, both deletions and duplications. As with most CPEO and KSS patients, Pearson patients are generally isolated cases, suggesting mutational events early in development (746,803–805). Moreover, autopsy analysis of Pearson patients has revealed that the mtDNA rearrangements are not simply localized to the bone marrow, but are systemic (806,807), and the rare Pearson patients who spontaneously recover the ability to make blood cells and survive ultimately progress to a KSS-like phenotype (758,801,808). These observations suggest that the Pearson marrow–pancreas syndrome and CPEO-KSS are the same disease, with the phenotypic differences resulting from the distribution of the rearranged molecules in the different tissues. This interpretation is supported by the observation that some Pearson patients, including those who have progressed to KSS, harbor duplications as well as deletions (756,758).

One explanation for the difference between Pearson syndrome and KSS-CPEO is that, in Pearson syndrome, the rearranged mtDNAs are widely distributed and include all of the bone marrow precursor cells. As the bone marrow stem cells replicate, the rearranged mtDNAs accumulate until there is insufficient energy for further proliferation and/or maturation. At this point, the rearranged molecules are prevalent in the peripheral blood and blood cell production declines, leading to pancytopenia. By contrast, in KSS-CPEO patients—or in Pearson syndrome patients who survive and progress to KSS—the rearranged molecules may be distributed such that a portion of the bone marrow precursor cells are free of mutant mtDNAs. As the stem cells containing rearranged molecules decline in their replicative potential, the cells having only normal mtDNAs continue to proliferate and ultimately supplant the mutant cells and repopulate the bone marrow. At this point, the patient loses the rearranged mtDNAs in the circulating white blood cells, but still retains rearranged mtDNAs in other organs. These later mutant mtDNAs exert their effects later in life, leading to the multisystem diseases of KSS and CPEO.

## 11.2 INHERITED NDNA MITOCHONDRIAL DISEASES

A recent count reported that mutations in 228 nuclear genes have been identified that cause non-genic mitochondrial diseases (809). These can affect structural and assembly genes of OXPHOS, mitochondrial biogenesis, maintenance, protein import, fusion–fission, and mobility (412,810).

### 11.2.1 Mutations In OXPHOS Structural Genes

Mutations in the nDNA-encoded structural genes of OXPHOS enzyme complexes generally result in LS, a frequently lethal childhood disease involving ophthalmoplegia and ptosis, hypotonia, progressive loss of motor and intellectual milestones, and bilateral lesions in the basal ganglia frequently leading to death (see Table 11-4). LS is a common presentation for boys with mutations in the X-linked  $E1\alpha$  subunit of PDH (585). Moreover, LS has been reported to result from mutations in the complex I *NDUFS1*, *NDUFS3*, *NDUFS4*, *NDUFS7*, *NDUFS8*, *NDUFV1*, *NDUFA1*, *NDUFA2* and *NDUFA10* genes (55,58,587,811–814) (see Table 11-4). Both *NDUFS6* and *NDUFA11* mutations have been reported associated with fatal infantile lactic acidosis (815,816). More recently, a homozygous mutation in the *NDUFB3* gene was identified in a patient with a severe complex I deficiency and lactic acidosis resulting in early death at 4 months of age (817). Moreover, mutations in the *NDUFS2* and *NDUFV2* genes have been reported to cause cardiomyopathy, hypotonia, and encephalomyopathy (818,819).

LS was also the phenotype of two brothers harboring mutations in the complex II SDH-A subunit (589). However, mutations in the other complex II subunits do not give LS but instead result in paraganglioma and pheochromocytoma. Reasons for this unexpected outcome are discussed in Section 11.5.

Finally, mutations in two of the subunits of complex III, UQCRB, have been linked with hypoglycemia and lactic acidosis (820) and UQCRCQ linked with a severe neurological phenotype (821). All of the nDNA-encoded diseases are Mendelian recessives, indicating that the phenotype is the result of loss of function mutations.

Examples of LS patients resulting from complex I gene mutations include a patient who was a compound heterozygote for mutations in the *NDUFS8* gene (TYKY or 23-kDa subunit). *NDUFS8* contains two 4Fe–4S ferredoxin consensus motifs, potentially forming the binding site for the N-2 iron–sulfur cluster. The missense mutations in the two alleles were Pro79Leu and Arg102His, resulting in a severe clinical phenotype (587). Finally, one patient presented with late-onset LS. This patient was found to be a compound heterozygote (P85L and R138H) for a mutation in the *NDUFS8* gene (822) (see Table 11-4).

Two other LS cases resulting from complex I mutations were homozygous for a missense mutation changing a Val122Met in the *NDUFS7* gene (58).

Four additional pathogenic mutations have been reported in nDNA complex I subunits in children with progressive degenerative disease. These children had a variety of symptoms, many reminiscent of LS, including hypotonia, feeding problems, vomiting, strabismus, myoclonic epilepsy, and MRI findings including basal ganglia abnormalities and atrophy. The complex I genes affected are for the *NDUFS4* 18-kDa protein (5-bp duplication) (823), the *NDUFV1* gene (two compound heterozygotes for Arg59Stop + Thr423Met), and the *NDUFV1* gene (Ala341Val) (58).

The most detailed report of an nDNA complex I mutation patient involved the *NDUFS4* gene (18-kDa subunit) resulting from a 5-bp duplication. This child presented with hypotonia, mental retardation, convulsions, and brain and basal ganglia degeneration. The patient was found to be homozygous for a 5-bp duplication that resulted in a frameshift at codon Lys158, causing a change in the amino acid sequence of the protein from amino acid 178 to the end. This frameshift destroyed a consensus phosphorylation site and extended the protein by 14 amino acids. The *NDUFS4* complex I gene was mapped to chromosome 5 (823) (see Table 11-4).

The LS complex II mutation altered the SDH-A gene on chromosome 5p15 and was observed in two siblings. The proband had isolated complex II deficiency in skeletal muscle, cultured skin fibroblasts, and circulating lymphocytes, with the enzyme showing a heightened sensitivity to oxaloacetate, the physiologic inhibitor. The causal mutation was a C-to-T transition at nucleotide 1684 in the cDNA, resulting in an Arg544Trp substitution in a highly conserved domain of the protein. Both siblings were homozygous mutants, while the two parents were heterozygotes (589) (see Table 11-4).

A homozygous mutation in *COX6B1* a complex IV structural subunit was identified in a consanguineous family with progressive neurologic phenotype, lactic acidosis, and leukodystrophic brain changes, resulting in a significant reduction of activity and assembly of complex IV (824). Complex V deficiency was also associated with a mutation in *ATP5E* gene and responsible for neonatal-onset lactic acidosis, peripheral neuropathy, and a mild mental retardation (825).

### 11.2.2 Mutations in Assembly Genes

Mutation in nDNA genes affecting the OXPHOS complexes have also been discovered in assembly genes for all complexes of the respiratory chain (see Table 11-5). Mutations in complex I assembly genes *NDUFAF1*, *NDUFAF2*, *NDUFAF3*, *NDUFAF4*, *NUBPL*, *ACAD9*, *C20orf7*, and *FOXRED1* have been found to be associated with early-onset encephalomyopathy, hypertrophic cardiomyopathy, and LS (88,826–832).

TABLE 11-5		Nonstructural Nuclear Genes—Cont'd				
Complex	Name	OMIM	Function	Chromosome	Inheritance	Clinical Phenotype
Iron homeostasis	<i>FRDA</i>	606829	Frataxin Trinuc. repeat	9q13	AR	Friedreich ataxia, neuropathy, cardiomyopathy, diabetes
	<i>ABCB7</i>	301310	Iron transport	Xq13.1-q13.3	X-linked	X-linked sideroblastic anemia with ataxia
	<i>GLRX5</i>	205950	Iron–sulfur cluster biosynthesis	3p22.1	AR	Sideroblastic anemia
	<i>ISCU</i>	255125	Iron–sulfur cluster biosynthesis	12q23.3	AR	Myopathy, lactic acidosis, intolerance
	<i>BOLA3</i>	613183	Iron–sulfur cluster biosynthesis	2p13.1	AR	Encephalomyopathy, cardiomyopathy
	<i>NFU1</i>	608100	Iron–sulfur cluster biosynthesis	2p13.3	AR	Lactic acidosis, multiple respiratory chain deficiency
Coenzyme Q10 biogenesis	<i>COQ2</i>	609825	CoQ10 deficiency	4q21-q22	AR	Encephalomyopathy, neuropathy
	<i>COQ4</i>	612898	CoQ10 deficiency	9q34.13	AR	Encephalomyopathy, mental retardation
	<i>COQ9</i>	612837	CoQ10 deficiency	16q13	AR	Neonatal lactic acidosis, cardiomyopathy
	<i>APTX</i>	606350	CoQ10 deficiency	9p13.3	AR	Cerebellar ataxia, oculomotor apraxia
	<i>PDSS1</i>	607429	CoQ10 deficiency	10p12.1	AR	Deafness, valvulopathy, mental retardation
	<i>PDSS2</i>	610564	CoQ10 deficiency	6q21	AR	LS, nephrotic syndrome
	<i>CABC1</i>	606980	CoQ10 deficiency	1q42.2	AR	Cerebellar ataxia, lactic acidosis
Chaperone function	<i>SPG7</i>	607259	Paraplegin ATPase protease	16q24.3	AR	Spastic paraplegia
	<i>HSPD1</i>	118190	Mitochondrial chaperone	2q33.1	AR	Spastic paraplegia, leukodystrophy
Mitochondrial integrity	<i>OPA1</i>	165500	Dynamin-related protein	3q28-q29	AD	AD–optic atrophy, multiple deletions
	<i>MFN2</i>	609260	Mitofusin Mitochondrial fusion	1p36-p35	AD	Charcot–Marie–Tooth disease-2A2 (CMT2A)
	<i>DLP1</i>	603850	Mitochondrial and peroxisomal fission	12p11.21	AD	multiple deletions, microcephaly
	<i>G4.5 (Tafazzin)</i>	302060	Cardiolipin defect	Xq28	X-linked	Microcephaly, abnormal development, optic atrophy, lactic acidosis
	<i>RMRP</i>	250250	RNAse Mitochondrial RNA processing	9p13-p12	AR	Barth syndrome, X-linked cardiomyopathy
Mitochondrial metabolism	<i>PDHA1</i>	308930	Pyruvate dehydrogenase E1- $\alpha$ subunit	Xp22.2-p22.1	X-linked	Metaphyseal chondrodysplasia–hair hypoplasia
	<i>ETHE1</i>	602473	Ethylmalonic acid metabolism	19q13	AR	LS
	<i>PUS1</i>	600462	Pseudouridine synthase	12q24.33	AR	Encephalopathy, ethylmalonic aciduria
						Myopathy, lactic acidosis, sideroblastic anemia

LS, Leigh syndrome; SANDO, Sensory Ataxic Neuropathy, Dysarthria, and Ophthalmoparesis; SCAE, Spinocerebellar Ataxia with Epilepsy; GRACILE syndrome, Growth Retardation, renal overgrowth, Lactic acidosis, and Early death; MNGIE, Mitochondrial NeuroGastroIntestinal Encephalopathy; MDDS, Mitochondrial DNA Depletion Syndrome.

Mutations in the *SDHAF1* assembly gene were identified responsible for a progressive neurologic deterioration during the first year of patient life associated with leukodystrophic brain abnormalities (833). Similar to SDH-B, -C, and -D, mutation in *SDHAF2* another complex II assembly subunit results in paraganglioma (834).

Similarly, a mutation in the *BCS1L* gene on chromosome 2q33 resulted in different phenotypes such as encephalomyopathy, hepatic failure, renal dysfunction, LS, and GRACILE or Björnstad syndromes (117,118,835).

The eight complex IV assembly genes that have been found to be mutant in patients fall into four categories: assembly, copper transport, heme a synthesis, and complex IV regulation. Mutation in the complex IV assembly gene *SURF1* has been observed in multiple LS families with complex IV deficiency. The *SURF1* gene is located on chromosome 9q34. The reported *SURF1* mutations included nonsense mutations, missense mutations, and frameshift mutations resulting from small insertions and deletions (158,159,251,836).

Defects in two copper transport protein genes (*SCO1* and *SCO2*) have also been found to result in complex IV deficiency. Infants with mutations in the *SCO2* gene present with lethal hypertrophic cardiomyopathy, lactic acidosis, neurodegeneration and atrophy, and hepatomegaly associated with a complex IV defect (see Table 11-5). To date, patients with pathogenic *SCO2* mutations always have one allele with the E140K missense mutation. The other allele has been either a null allele or another missense mutation (e.g. S225F or R171W) (165). Interestingly, in the yeast model system, the equivalent of the E140K mutation does not significantly reduce complex IV activity, while the S225F mutation results in respiratory deficiency. Yeast with the S225F mutation assembles complex IV without the mtDNA COII subunit. This suggested that *SCO2* is involved in the insertion of Cu<sup>2+</sup> into the Cu<sub>A</sub> site of the mtDNA COII subunit (164).

Infants with mutations in the *SCO1* gene develop hepatic failure and encephalomyopathy with a complex IV defect due to faulty Cu<sup>2+</sup> incorporation (see Table 11-5). Patients have been found to have compound heterozygous mutations including frameshift and missense mutations. Two identified missense mutations are C250T and P174L, the latter mutation being thought to affect the copper-binding domain (CXXXC) of the enzyme (166).

Mutations in two other nDNA genes (*COX10* and *COX15*) inhibit the synthesis of complex IV heme a. The index case harboring mutant *COX10* genes presented with ataxia, severe hypotonia, ptosis, pyramidal syndrome, status epilepticus, and proximal tubulopathy and died at 2 years (see Table 11-5). He had an older sister who died at 5 years of mitochondrial encephalopathy associated with complex IV deficiency, and a younger sister who had progressive neurologic deterioration

and died at 3 years. Genetic analysis revealed that these patients were homozygous for a deleterious missense mutation (N204K) in the *COX10* gene. The parents were both heterozygous for this mutation. *COX10* encodes the heme a:farnesyltransferase enzyme, and the patients have a 50% reduction in complex IV subunits III and IVc and more than 97% reduction in subunit II (166).

Mutations in the *COX15* gene on chromosome 10q24 result in the inhibition of heme a synthesis. Patients with defects in this gene develop early-onset hypertrophic cardiomyopathy or LS (837). Mutations in the *LRP-PRC* gene on chromosome 2p21-p16 were described in a large series of French Canadian patients associated with a cytochrome oxidase assembly deficiency and LS (838). The LS phenotype was also linked to mutations in *TACO1* required for efficient translation of COX1 an mtDNA-encoded subunit, critical for complex IV assembly (839). A mutation in *FASTKD2* which was located on chromosome 2q33.3 was found to be responsible for an encephalomyopathy and suggested to regulate mitochondrial apoptosis (840).

Finally, a complex V assembly gene, *ATPAF2*, has been identified on chromosome 17p11.2. Defects in this gene are associated with early-onset encephalomyopathy with lactic acidosis (198). Another complex V assembly gene *TMEM70* was found to be defective in a large series of patients affected with neonatal mitochondrial encephalocardiomyopathy and severe complex IV deficiency (841).

### 11.2.3 Mutations in Mitochondrial Protein Metabolism and Assembly

Mutations in nDNA-encoded genes involved in mitochondrial biogenesis, assembly, and turnover have also been identified. The first-discovered pathologic mutation in an nDNA protein biogenesis gene occurred in the mitochondrial protein synthesis elongation factor G1. Inactivation of this gene in chromosome 3q25 results in lactic acidosis in association with severe liver and central nervous system disease (198).

The translational machinery requires a large variety of nuclear-encoded subunits including aminoacyl-tRNA synthetases, initiation, elongation, and termination factors. Mutations in the genes encoding mitochondrial aminoacyl-tRNA synthetases have been described for *YARS2*, *SARS2*, *DARS2*, *RARS2* linked to a variety of phenotypes such as myopathy, pulmonary hypertension, or pontocerebellar hypoplasia (842–845).

A homozygous nonsense mutation in the *MRPS16* gene was discovered in a patient affected with fatal neonatal lactic acidosis and agenesis of the corpus callosum, resulting in a defect in mitochondrial translation. Another mutation in the *MRPS22* gene was associated with cardiomyopathy and tubulopathy and a combined OXPHOS defect (846).

Mitochondrial translation elongation factors have been also associated with encephalomyopathy, hypertrophic cardiomyopathy, leukodystrophy with micropolygyria due to mutations in *TSM* and *TUFM* genes, respectively (847,848).

The first nDNA mutation that affects mitochondrial protein import has been localized to the *DFN-1* gene and causes the Mohr–Tranebjaerg syndrome, encompassing dystonia and deafness. The Mohr–Tranebjaerg syndrome presents in early childhood with sensorineural hearing loss that can progress to dystonia, spasticity, mental deterioration, paranoia, and cortical blindness. Those patients who develop the movement disorder characteristically exhibit progressive degeneration of the basal ganglia, corticospinal tract, and brain stem. The Mohr–Tranebjaerg syndrome gene is located on the X chromosome, and the index case was found to have a 10-bp deletion in exon 2 of the *DFN1* gene. The identity of the gene was confirmed in a second family found to harbor a 1-np deletion in exon 1. *DFN1* generates a 1167-np cDNA encoding a 97-amino acid, 11-kDa polypeptide designated DDP1p. The predicted polypeptide has a high homology to a *Schizosaccharomyces pombe* gene of unknown function (849) (see Table 11-5).

A role for proteins of the DDP1 structure in mitochondrial protein import was demonstrated by studies of the yeast mitochondrial import proteins, while studying the *Saccharomyces cerevisiae* import pathway for mitochondrial inner membrane carrier proteins such as the ANT (yeast ACC) (256). DDP1 is the mammalian counterpart to the yeast protein Tim8p. Tim8p is a member of a family of proteins located in the mitochondrial intermembrane space that includes Tim8p, Tim9p, Tim10p, Tim12p, and Tim13p. All of these polypeptides are similar in size and contain a distinctive duplicated C(N)<sub>3</sub>C motif, reminiscent of a zinc finger protein. Surprisingly, the DDP1 protein of the Mohr–Tranebjaerg syndrome was found to have the same duplicated C(N)<sub>3</sub>C motif as the Tim8p family protein. Moreover, synthetic DDP1 is incorporated into the mitochondrial intermembrane space in yeast, and haptin-tagged DDP1 is specifically localized to yeast and mammalian mitochondria (256).

The Tim proteins form two similar 70-kDa complexes in the mitochondrial inner membrane. The Tim9p–Tim10p complex is important for the import of most of the inner membrane carriers including the ANT, phosphate carriers, and dicarboxylate carrier. However, the Tim8p–Tim13 (DDP1–TIMM13) complex is important in the import of the Tim23p (TIMM23) and in the early steps of the biogenesis of Tom40p of the TOM complex. In addition, this complex is involved in the import into the mitochondria of two calcium-responsive aspartate/glutamate carriers, citrin and aralar1. These are components of the malate-aspartate NADH shuttle. Moreover, DDP1 and TIMM13 are preferentially expressed in the

brain and particularly in large neurons such as Purkinje cells. Thus, it would appear that the pathophysiology of Mohr–Tranebjaerg syndrome is impaired NADH transport between the cytosol and the mitochondria (850).

The demonstration that inactivation of the DDP1 protein would compromise mitochondrial biogenesis and in turn bioenergetics of neurons, resulting in deafness and dystonia, is consistent with the fact that the mtDNA mutation MTND6\*LDYT14459A, which impedes mitochondrial complex I (NADH dehydrogenase), also results in dystonia. Thus, both nDNA and mtDNA mutations that affect NADH metabolism in the brain can cause the same phenotype.

The DNAJC19 protein shares similarity with the yeast TIM14 protein, a component of the mitochondrial protein import system. Defective *DNAJC19* gene has been linked to an autosomal recessive disorder with early onset dilated cardiomyopathy, ataxia, and significant increases of 3-methylglutaconic acid and 3-methylglutaric acid in urine organic acids (851).

The first nDNA mutations associated with a defect in mitochondrial protein turnover result in hereditary spastic paraplegia (HSP). HSP, in the “pure” form, presents primarily with progressive weakness and spasticity of the lower limbs. However, in the “complicated” form, symptoms can include mental retardation, peripheral neuropathy, amyotrophy, ataxia, retinitis pigmentosa, optic atrophy, deafness, and ichthyosis. Muscle histology of patients in one mutant family revealed RRFs, which were SDH hyperreactive and contained packed abnormal mitochondria. HSP was initially found to be linked to the paraplegin gene (SPG7) on chromosome 16q24.3 in a large Italian family (852). The paraplegin gene consists of five exons extending over 10.8 kbp of genomic sequence. The index family was found to harbor a complex rearrangement in the gene, possibly associated with the interactions of multiple Alu repeat elements. Paraplegin mutations have also been observed in two additional families: a homozygous 2-bp deletion causing a frameshift that abolished 60% of the protein, and a single A insertion that created a frameshift and stop codon two amino acids downstream, thus removing the C-terminal 57 amino acids. The paraplegin protein is an 88-kDa polypeptide with a 40- to 45-amino acid targeting peptide. It shows homology to a subfamily of adenosine triphosphatases (AAA proteins) that are yeast mitochondrial metalloproteases. In yeast, such proteins have both protease and chaperone-like activities (852). Thus, the paraplegin protein may function in the assembly and degradation of mitochondrial enzyme complexes. Spastic paraplegia and leukodystrophy were also linked to mutations in *HSPD1* gene in a large consanguineous family (853).

Primary CoQ deficiency resulting from defects in one of the several steps involved in the CoQ biosynthesis is rare. Primary CoQ deficiency syndromes are also heterogeneous, presenting with encephalomyopathy, LS,

nephritic syndrome, severe multisystem infantile disease, cerebellar ataxia, or pure myopathies (854–860). However, when the diagnosis of primary CoQ deficiency is made, the patient can benefit from CoQ10 supplementation.

### 11.2.4 Mutations that Alter Mitochondrial Physiology

Three nDNA gene mutations that alter mitochondrial metabolism are particularly relevant: Barth syndrome, ethylmalonic aciduria, and Friedreich ataxia. Barth syndrome is an X-linked disease associated with dilated cardiomyopathy. The mutant protein Tafazzin is involved in cardiolipin synthesis, and cardiolipin is a specific and essential component of the mitochondrial inner membrane. Presumably loss of Tafazzin then inhibits mitochondrial function in the heart, resulting in the phenotype (861,862).

Ethylmalonic aciduria together with encephalopathy has been discovered to be due to mutations in a gene located on chromosome 19q13, and all types of mutations—missense, stop, frameshift, and splice mutations—have been identified in patients affected by ethylmalonic encephalopathy. This *ETHE1* gene results in strikingly elevated ethylmalonate in the urine. This elevation might be related to the gene defect altering glutathione metabolism. If so, then this may be a disease resulting from increased oxidative stress (863,864).

Mitochondria are also centrally involved in iron metabolism. Diseases those are associated with a dysregulation of mitochondrial iron, as in the case of Friedreich's ataxia, which is caused by a deficiency in frataxin, a regulator of mitochondrial iron processing. Patients with Friedreich ataxia manifest cerebellar ataxia, peripheral neuropathy, hypertrophic cardiomyopathy, and diabetes as the result of inactivation of the frataxin gene on chromosome 9q13. The frataxin gene contains an intron trinucleotide repeat that, when expanded, inhibits gene expression. Repeat expansion of both alleles lowers frataxin protein levels sufficiently to result in the disease. Frataxin binds iron in the mitochondrial matrix, thus minimizing mitochondrial OH production. The loss of the frataxin protein results in excessive ROS generation, which inactivates all mitochondrial iron–sulfur-containing enzymes, including complexes I, II, III, and aconitase. Thus, Friedreich ataxia appears to be the result of increased mitochondrial ROS production and decreased mitochondrial OXPHOS (22,865,866).

In addition to frataxin, there are other proteins that govern the tightly regulated processes of mitochondrial iron utilization. Mutations in *ABCB7*, *GLRX5*, *ISCU*, *BOLA3*, and *NFU1* genes involved in iron transport or Fe-S cluster biogenesis cause distinctive human diseases from sideroblastic anemia, myopathy, encephalopathy, cardiomyopathy, and multiple respiratory chain deficiency (867–870).

### 11.2.5 Mutations that Affect mtDNA Fusion and Fission

Autosomal dominant optic atrophy and a form of Charcot–Marie–Tooth disease have been found to result from defects in mitochondrial fission and fusion (see Table 11-5). Dominant optic atrophy is phenotypically very similar to LHON, with a midlife sudden onset of central vision loss. However, instead of being maternally inherited, it is inherited as an autosomal dominant. The majority of dominant optic atrophy cases are due to mutations in the *OPA1* gene, a dynamin-related GTPase located on chromosome 3q28–q29. This protein appears to be important in mitochondrial fission (871,872). It was demonstrated that *OPA1* mutations can be responsible for syndromic forms of autosomal dominant optic atrophy associated with sensorineural deafness, ataxia, axonal sensory motor polyneuropathy, CPEO, and MM with cytochrome c oxidase (COX)-negative and ragged red fibers, called dominant optic atrophy “plus” phenotypes. These phenotypes are related to mtDNA instability resulting in multiple mtDNA deletions emphasizing the role of *OPA1* in mtDNA maintenance (873).

The peripheral neuropathy Charcot–Marie–Tooth disease can result from mutations in a variety of genes. However, Charcot–Marie–Tooth type 2A2 results from inactivation of the mitofusin 2 gene (*MFN2*). Mitofusin, which is located on chromosome 1p35–p36, is essential for mitochondrial fusion (874,875). Presumably, the loss of the appropriate mitochondrial fission–fusion cycle in the neurons alters the ability of the mitochondria to be appropriately distributed throughout the neuron, resulting in localized energy deficiency and impaired neuronal function.

Recently, a mutation in *MFN2* in a large three generational family with optic atrophy was associated with axonal neuropathy and MM. Similar to *OPA1* mutations, the “plus” phenotype was linked to mtDNA instability resulting in multiple mtDNA deletions in patient skeletal muscle (876).

Mutation in another dynamin *DLP1* has been associated with defective mitochondrial and peroxisomal fission. A heterozygous dominant-negative mutation in the *DLP1* gene was responsible for microcephaly, abnormal brain development, optic atrophy, and lactic acidosis in a newborn that died after 3 weeks of life (877).

### 11.2.6 Mutations Affecting mtDNA Stability and Expression

A variety of nDNA defects have now been identified, which affect the replication of mtDNA. These can be grouped into five phenotypic categories: chondrodysplasia, intestinal dysmotility, brain and liver dysfunction, multiple mtDNA deletions, and mtDNA depletion.

Metaphyseal chondrodysplasia, or cartilage-hair hypoplasia, has been discovered to be due to mutations

in the MRP RNase. Cartilage-hair hypoplasia is an autosomal recessive disorder associated with disproportionate short stature, hypoplastic hair, ligamentous laxity, defective immunity, hypoplastic anemia, and neuronal dysplasia of the intestine. These problems can be manifested as congenital megacolon (Hirschsprung disease) and predisposition to lymphomas and other cancers. The disease is remarkable in its clinical variability within and between pedigrees. The RNase MRP has been proposed to cleave the nascent mtDNA L-strand transcript to generate a primer for initiating H-strand replication, though the protein is also present in the nucleus. The enzyme includes an RNA component that is located on chromosome 9p13 and transcribed by RNA polymerase III. Two classes of mutations have been identified: deletions between the promoter and the transcription start site, which result in null mutants, and base substitutions in the structural RNA. Four structural mutations have been identified, two of which alter bases in single-stranded loops and a base substitution and a two-base insertion that affect double-stranded components of the RNA (878). While the pathophysiology of this disease is currently unknown, it is interesting that many of the symptoms associated with this disease are also seen in other mitochondrial diseases. Hence, it is possible that mitochondrial deficiency may play an important role in this disease process.

Intestinal dysmotility is the hallmark of MNGIE, which is associated with MM, including RRFs and abnormal mitochondria; decreased respiratory chain activity; and multiple mtDNA deletions, mtDNA depletion, or both. This autosomal recessive disease has been linked to multiple mutations in the nuclear TP gene. While the disease is caused by TP mutations, the clinical symptoms are probably the result of the destruction of mtDNA. Hence, it has been hypothesized that inactivation of TP alters cellular thymidine pools, which are important in mtDNA maintenance (879) (see Table 11-5).

Alpers disease is associated with generally lethal encephalopathy associated with white matter lesions and liver dysfunction. This autosomal recessive disorder is now known to result from null mutations in the mtDNA POLG gene, located on chromosome 15q25 (880). However, mutations in the POLG gene have also been shown to result in a variety of other clinical phenotypes, including autosomal dominant or recessive PEO (881,882), sensory ataxic neuropathy, dysarthria, and ophthalmoparesis (SANDO), and spinocerebellar ataxia with epilepsy (883). Of the PEO cases seen in the clinic, ~6% have been found to harbor multiple deletions and show a clear autosomal dominant inheritance pattern. Such families are described as having autosomal dominant-PEO (AD-PEO) (678,768,884,885) AD-PEO with multiple deletions can result from POLG, ANT1, and Twinkle helicase gene mutations (see Table 11-5).

In AD-PEO, each affected individual has a different array of mtDNA deletions. This demonstrates that it is

a nuclear mutation that increases the tendency toward deletion and that this tendency is inherited, not the deletion itself (768,884,885). Clinically, the mean age of onset of AD-PEO is 26 years, which is older than the average spontaneous CPEO case. In addition to PEO, these patients experience proximal muscle atrophy and weakness in about 62% of cases, hearing loss in 25%, and ataxia in 17% of cases. Cardiac and retinal involvements are rare, and the most common cause of death is respiratory failure (886). Multiple deletions have also been found in four patients with RRFs but atypical neurologic symptoms. Two individuals presented with parkinsonism, one with ptosis, a third with exercise intolerance and limb weakness, and a fourth with elevated blood creatine phosphokinase (887). The nature of the deletions in multiple deletion syndrome is similar to that found in spontaneous deletion patients. Among the 81 deletions reported from multiple deletion syndrome patients, 96% are encompassed by direct repeats of 4–13 nucleotides, while 4% involve indirect repeats of 4 base pairs (281). Moreover, patients show multiple deletions in tissues throughout the body (888).

Mutation in POLG appears to be the most common cause of AD-PEO with multiple mtDNA deletions. POLG maps to chromosome 15q25, and a wide variety of POLG mutations have now been identified with various disease phenotypes, as discussed in W. Copeland's website (<http://tools.niehs.nih.gov/polg/>). In all of these cases of AD-PEO, the damaged POLG results in instability of the mtDNA template leading to multiple mtDNA rearrangement mutations, known as multiple deletions syndromes. The clinical phenotype of AD-PEO patients resulting from POLG mutations primarily involves MM. The POLG gene also encompasses a trinucleotide repeat, and alteration in the repeat length has been implicated in male sterility (889).

A mouse has been generated in which the proofreading function has been inactivated by knocking into the chromosomal POLG locus the D257A mutation in the 3'-to-5' exonuclease. These mice had a shortened life span and developed a premature aging phenotype involving weight loss, reduction of subcutaneous fat, hair loss (alopecia), curvature of the spine (kyphosis), osteoporosis, anemia, reduced fertility, and heart enlargement. This was associated with an age-related decline in respiratory complexes I and IV and in mitochondrial ATP production rates in the heart. Analysis of the mtDNA revealed that the knock-in animals had a three- to fivefold increase in mtDNA base substitution mutations in brain, heart, and liver, with a higher number of mutations in the CR cytochrome b gene than in the mtDNA CR (497). Thus, increased mtDNA mutations can directly increase the aging rate, implying that mtDNA is one of the most important targets for mitochondrial ROS damage in aging.

The DNA polymerase gamma is also composed of two different subunits: a 140-kDa catalytic subunit (POLG1)

and a 55-kDa accessory subunit (POLG2). A patient with typical late-onset PEO carried a heterozygous mutation changing a glycine in glutamate at position 451 in the POLG2 gene (890).

The second major locus causing a multiple deletions syndrome was mapped in a Finnish study at chromosome 10q23.3-24.3 (891,892). This was subsequently shown to be the result of mutations in the mtDNA Twinkle helicase, giving AD-PEO and SANDO (893,894). Twinkle is homologous to the bacteriophage T7-type pg4 hexameric primase-helicase. It interacts with POLG from the core of the mtDNA replicasome. Patients with Twinkle mutants develop AD-PEO, but can also develop major depression (895) (see Table 11-5).

Transgenic mouse models of AD-PEO caused by Twinkle mutations were prepared by pronuclear injection of a transgene with a milder A360T mutation and a more severe in-frame duplication of amino acids 353 through 365. Both transgenic mouse models accumulated multiple mtDNA deletions, and the duplication mouse model also showed mtDNA depletion, though the mice did not have heightened mtDNA base substitution mutations. The Twinkle duplication mutation developed COX<sup>-</sup> and SDH<sup>+</sup> muscle fibers by 18 months, with abnormal mitochondria containing spiral cristae, though not paracrystalline precipitates. Moreover, the Twinkle duplication mice showed that, by 18 months, about 1% of the Purkinje cells were COX<sup>-</sup>, SDH<sup>+</sup> and that occasional COX<sup>-</sup>, SDH<sup>+</sup> cells were seen in the olfactory bulbs, substantia nigra, and hypothalamus. Moreover, numerous COX<sup>-</sup>, SDH<sup>+</sup> cells were epithelial cells of the choroids plexus. None of the mice developed the muscle weakness seen in humans, but the neurologic pathology provides a possible explanation for the depression seen in the Twinkle mutant patients (896).

A third AD-PEO locus, which mapped to chromosome 4q34-35 (897,898), proved to be ANT1 (see Table 11-5). Two missense mutations have been identified. One was found in five Italian families with a common background haplotype, suggesting that they are related by descent. This mutation changes a highly conserved alanine at codon 114 to a proline. The second mutation was identified in a single individual and changed the valine at codon 289 to a methionine (899). The various ANT1 mutations associated with AD-PEO have proven to be missense mutations (A114P, V289M, L98P, D104G, and A90D). Furthermore, modeling of these mutations in yeast has revealed that they are acting as dominant-negative mutants (899–902).

On the other hand, a single patient has been identified who was homozygous for a null missense mutation. This individual manifested cardiomyopathy and MM with multiple deletions, but did not exhibit ophthalmoplegia (903). Interestingly, this is the same phenotype that was obtained when the Ant1 locus was knocked out in mouse (227) in two ways: by homologous recombination knockout with a neomycin gene driven by the PGK

promoter (PGK-neo) and by knock-in with a promoterless  $\beta$ geo cassette. Staining of adult tissues revealed strong expression in heart, muscle, and brain. Pathologic analyses of the Ant1<sup>-/-</sup> mice revealed the presence of cardiomyopathy and MM, the latter with classical RRFs and markedly increased COX and SDH staining in the type I oxidative fibers, and a massive proliferation of giant, swollen mitochondria. When subjected to an exercise stress test, the Ant1<sup>-/-</sup> animals were found to be highly fatigable, collapsing after half the exercise regimen of the Ant1<sup>+/+</sup> animals (227). Ant1 expression was confirmed in the extraocular eye muscles using the Ant1  $\beta$ geo mice, and Ant1 deficiency was associated with MM with increased COX and SDH staining and enlarged abnormal mitochondria. However, the Ant1 defect did not affect extraocular eye movement (904). This is the same phenotype seen in the ANT1-null patient (903).

Analysis of the hearts of 4- to 6-month-old Ant1<sup>-/-</sup> mice revealed a classical hypertrophic cardiomyopathy. Ultrastructural analysis revealed a partial reduction in contractile elements and a substantial induction of mitochondrial proliferation. As Ant1<sup>-/-</sup> mice age, they progress from hypertrophic cardiomyopathy at 3 months to dilated cardiomyopathy after 15 months (905).

Physiologic analysis of the Ant1<sup>-/-</sup> animals revealed elevated urine lactic acid, alanine, citrate, and succinate. Furthermore, ADP normally stimulated respiration in Ant1<sup>-/-</sup> liver mitochondria, partially stimulated respiration in the heart mitochondria, but had no effect of respiration in muscle mitochondria, consistent with the tissue distribution of Ant1. Analysis of mitochondrial H<sub>2</sub>O<sub>2</sub> production in the Ant1<sup>-/-</sup> tissue mitochondria revealed substantial ROS production in skeletal muscle, heart, and brain mitochondria, thus confirming that Ant1 deficiency is metabolically affecting brain, muscle, and heart. Consistent with the increased ROS production, glutathione peroxidase expression was increased in heart and muscle and MnSOD was increased in muscle. Moreover, the level of mtDNA rearrangements was greatly increased in the hearts of 15-month-old Ant1<sup>-/-</sup> mice (227).

As in the case of MNGIE-associated thymidine phosphorylase (TYMP) mutations that cause both mtDNA multiple deletions and mtDNA depletion, nDNA mutations have been identified in several other mitochondrial enzymes—ANT1 (899), thymidine kinase (TK2) (837), deoxyguanosine kinase (DGUOK) (906) and MPV17 (907), ribonucleotide reductase M2B (908) succinyl-CoA ligase subunits (909,910)—that are involved in mtDNA substrate provision through the maintenance of mitochondrial deoxyribonucleotide pool for mtDNA synthesis resulting in mtDNA depletion (see Table 11-5).

Mitochondrial depletion is associated with early childhood, frequently lethal, respiratory failure, lactic acidosis, and selective organ failure involving muscle (MM), heart, liver, or kidney (911–919).

Hence, in mtDNA depletion syndrome, organ failure is associated with a severe diminution of the level

of mtDNA relative to nDNA in the affected tissue. This has been documented by molecular hybridization of mtDNA and 18S rRNA sequences to Southern blots of PvuII digests followed by determining the ratio of hybridization by densitometry (915,918) or by dot-blot hybridization using a  $^{35}\text{S}$ -dCTP-labeled mtDNA probe and a  $^{32}\text{P}$ -dCTP-labeled arginosuccinate synthetase gene probe (916). Depletion has been confirmed by demonstrating the loss of mtDNA gene products and loss of cytoplasmic mtDNA by immunohistochemistry (915,918).

The age of onset and severity of symptoms vary among patients, and these variations have been loosely correlated with the severity of the depletion. In one series of 10 patients, individuals exhibiting symptoms shortly after birth and dying in the first year of life had between 2% and 17% residual mtDNA in the affected organ, while individuals who exhibited symptoms after the first year and lived for three or more years had between 14% and 34% of the normal mtDNA (914,915,918). This association is less clear in another series of patients, although one complexity is the rapid rise in the mtDNA:nDNA ratio during the first 2–3 years of life (916).

## 11.3 MITOCHONDRIAL ETIOLOGY FOR COMMON METABOLIC AND VISCERAL DISEASES

### 11.3.1 Diabetes and Metabolic Syndrome

The linkage of mtDNA rearrangement (731,732) and tRNA mutations (730) to type 2 diabetes directly linked mitochondrial defects to common diseases. Evidence that mtDNA defects are a common factor in the etiology of diabetes comes from the observation that as the age-of-onset of the proband increases, the probability that the mother was the affected parent also increases, reaching a ratio of 3:1 for patients with a mean age-of-onset of 46 years (412). These observations can be linked to the larger human “metabolic syndrome” through the identification of a mtDNA tRNA<sup>Leu</sup> mutation at np 4291 (T>C) that causes hypertension, hypercholesterolemia, and hypomagnesemia (renal ductal convoluted tubule defect) in a maternal pedigree in association with reduced mitochondrial ATP production and the secondary clinical findings of migraine, hearing loss, hypertrophic cardiomyopathy, and MM (733).

Insights into how mitochondrial defects cause type 2 diabetes have been obtained from the analysis of the mitochondrial gene expression profiles of cells harboring different percentages of the tRNA<sup>Leu(UUR)</sup> 3243 mutation generated using transmitochondrial cybrids (288,289). The cybrids were generated from cells of a patient that was heteroplasmic for the tRNA<sup>Leu(UUR)</sup> A3243G mutation which were enucleated and the cytoplasts fused to a recipient 143B(TK-) osteosarcoma cell which lacked mtDNA ( $p^0$ ) (296). Cybrid clones were then selected for those with different percentages of mutant A3243G and

wild-type A3243A mtDNAs, and tested for the effect of the level of mutant heteroplasmy on the expression of nDNA and mtDNA mitochondrial genes using the MITOCHIP. The MITOCHIP is a custom cDNA microarray encompassing ~600 genes involved in mitochondrial bioenergetics, biogenesis, antioxidant defense systems, and apoptosis. Those cybrids with less than about 60% A3243G mtDNAs were found to have significantly downregulated about 40 nDNA-encoded mitochondrial genes, slightly downregulated selected mtDNA-encoded genes, and upregulation of a dozen nDNA genes. This experiment linked a partial mitochondrial protein synthesis defect with type 2 diabetes and with a downregulation of mitochondrial gene expression, suggesting that diabetes was a mitochondrial disease.

Consistent with these cellular results, studies of patients with type 2 diabetes have also revealed the downregulation of mitochondrial function and gene expression. Insulin-resistant offspring of type 2 diabetic patients have been found to have impaired mitochondrial energetics, as assessed by  $^{31}\text{P}$ -MR Spectroscopy (920). Furthermore, type 2 diabetes patients consistently show a downregulation of nDNA encoded mitochondrial gene expression, in association with alterations in the levels of the PPAR $\gamma$ -coactivator 1 (PGC-1) (921,922). The PPAR $\gamma$ -PGC-1 is a major regulator of mitochondrial biogenesis and fat oxidation (373,923).

Diabetes mellitus is also seen in Friedreich ataxia, caused by increased mitochondrial ROS production. Friedreich patients manifest cerebellar ataxia, peripheral neuropathy, hypertrophic cardiomyopathy, and diabetes as the result of inactivation of the frataxin gene on chromosome 9q13. Frataxin binds iron in the mitochondrial matrix thus minimizing mitochondrial OH production. The loss of the frataxin protein results in the ROS inactivation of all mitochondrial iron-sulfur containing enzymes including complexes I, II, III, and aconitase. Thus, increased mitochondrial ROS production and decreased mitochondrial OXPHOS have been linked to diabetes (22,865,866).

Type 2 diabetes has also been associated with a Pro121A polymorphism in the PPAR $\gamma$  (924). PPAR $\gamma$  is thought to play a role in the regulation of peroxisome and mitochondrial number and structure. Type 2 diabetes has also been associated with a Gly482Ser polymorphism in the PGC-1 in Danish populations (925) and in the Pima Indians (926).

Maturity onset of diabetes in the young (MODY) is an early-onset autosomal dominant form of type 2 diabetes that might also be linked to mitochondrial dysfunction. The molecular defects of four forms of MODY have been identified. MODY 2 is the result of mutations in glucokinase, MODY 1 due to mutations in the hepatocyte nuclear factor (HNF)-1 $\alpha$ , MODY 3 due to mutations in HNF-4 $\alpha$ , and MODY 4 due to mutations in insulin promoter factor (IPF)-1. Early indications are that these genes may modulate  $\beta$  cell mitochondrial

function. Glucokinase has a very high  $K_m$  for glucose and is thought to be the glucose sensor. Glucokinase may bind to mitochondrial VDAC such that the ATP binding site is fed mitochondrial ATP through the ANT (927–929). After a meal, when the serum concentration of glucose is high, glucose binds to glucokinase and is phosphorylated to glucose-6-phosphate (G-6-P). G-6-P is then converted to pyruvate for use in mitochondrial ATP generation (Figure 11-4).

Mutations in HNF-1 $\alpha$  are associated with post-pubertal diabetes, obesity, dyslipidemia, and arterial hypertension, all features of mitochondrial diseases. Moreover, HNF-1 $\alpha$  is also important in regulating nDNA encoded mitochondrial gene expression and the expression of GLUT 2 glucose transporters (930). HNF-4 $\alpha$ , a member of the steroid/thyroid hormone receptor super-family, acts as an upstream regulator of HNF-1 $\alpha$  (931). Therefore, the MODY 1, 2, and 3 genes appear to adversely affect mitochondrial function in the pancreatic  $\beta$  cells.

The importance of mitochondrial deficiency in defects in  $\beta$  cell insulin secretion has been confirmed in two mouse models. In the first, the mitochondrial transcription factor, Tfam, was inactivated in the pancreatic  $\beta$  cells. This resulted in increased blood glucose in both fasting and non-fasting states, and the progressive decline in  $\beta$ -cell mass by apoptosis (932). In the second, the ATP-dependent K<sup>+</sup>-channel ( $K_{ATP}$ ) affinity for ATP was reduced resulting in a severe reduction in serum insulin, severe hyperglycemic with hypoinsulinemia, and elevated D-3-hydroxybutyrate levels (933). These models demonstrate that mitochondrial ATP production is critical in the signaling system of the  $\beta$  cell to permit insulin release (934). Thus, pancreatic  $\beta$  cell mitochondrial defects are important in both glucose sensing through glucokinase and insulin releases through the  $K_{ATP}$  channel.

These observations lead to the following model of mitochondrial involvement in type 2 diabetes. On ingestion of a meal, the glucose concentration in the blood rises until it exceeds the  $K_m$  of the  $\beta$  cell glucokinase. Since glucokinase is bound to the mitochondrial VDAC, its ATP binding site is continuously occupied by mitochondria-derived ATP provided by ANT. The binding of glucose by glucokinase results in the production of G-6-P, which is then converted to pyruvate via the glycolytic pathway. Pyruvate is oxidized by the mitochondria to generate ATP. The elevated ATP production increases the ATP/ADP ratio which results in the closing of the  $K_{ATP}$  channel, depolarizing the  $\beta$  cell plasma membrane. The depolarized plasma membrane opens the voltage sensitive Ca<sup>++</sup> channel. The influx of Ca<sup>++</sup> stimulates the transport of insulin containing vesicles to the plasma membrane and thus the release of insulin (Figure 11-4).

These observations lead to the hypothesis that type 2 diabetes is a mitochondrial disease. In individuals who inherit mutations in nDNA or mtDNA mitochondrial genes, the partial defect in OXPHOS reduces the

capacity in their post-mitotic cells to oxidize carbohydrates and fats to make ATP. Given a high caloric diet, these individuals overload their mitochondrial capacity to oxidize the glucose associated reducing equivalents. The high circulating glucose signals the  $\beta$  cells to secrete insulin, resulting in concurrent elevated glucose and insulin, “insulin resistance.” The sustained high serum glucose and lipids result in the deposition of fats in storage tissues including liver resulting in nonalcoholic steatohepatitis (NASH), NASH being observed in over 30% of individuals with indications of insulin-resistance, hypertriglyceridemia, and hypercholesterolemia (935).

The high circulating glucose stimulates the  $\beta$  cells to secrete insulin. Insulin interacts with the insulin receptor of different target tissues to stimulate the storage of fats and glycogen and to downregulate mitochondrial energy metabolism, presumably through PPAR $\gamma$  and PGC-1. Moreover, the excess of reducing equivalents overloads the ETC elevating the NADH/NAD<sup>+</sup> ratio and driving mitochondrial ROS production. In the peripheral tissues, this further erodes mitochondrial function and increases insulin resistance. In the  $\beta$  cells, this erodes the mitochondrial ATP production capacity eventually leading to a decline in insulin secretion due to inadequate ATP for glucokinase and low ATP/ADP ratio which cannot activate the  $K_{ATP}$  channel. The high glucose but reduced insulin levels is termed “insulin-independent diabetes.”

Continued calorie overload in the  $\beta$  cells causing chronic mitochondrial ROS production ultimately activates the mtPTP which results in the death of the  $\beta$  cells by apoptosis, resulting in “insulin-dependent diabetes.” The chronic mitochondrial oxidative stress on the peripheral tissues ultimately results in damage to the retina, vascular endothelial cells, peripheral neurons, and nephrons leading to end stage diabetes. Therefore, these studies suggest that mild, chronic mitochondrial defects may be a primary cause of type 2 diabetes.

Haplogroup J has been associated with increased risk of diabetes in certain European descent populations (936–938), while haplogroup N9a is protective of diabetes, metabolic syndrome, and myocardial infarction in Asians (939–941). Haplogroups N9a and F have been shown to affect mitochondrial function through alterations in expression array studies confirming that the mtDNA haplogroups do contribute to the pathophysiology of diabetes and metabolic syndrome (942).

### 11.3.2 Ischemic Heart Disease and Dilated Cardiomyopathy

Ischemic heart disease results from the development of atherosclerotic plaques on the coronary arteries of the heart. When the arteries constrict, the plaques occlude the artery, blocking blood flow to the heart and starving the heart mitochondria of oxygen (ischemia). In the absence of oxygen, the ETC stops and, since fatty acids and hence reducing equivalents are abundant, the

electron carriers become fully reduced. On dilation of the coronary artery, blood flows back into the heart, supplying oxygen (reperfusion). At this point, electrons contained in reduced ubiquinone can be donated directly to oxygen to give a burst of superoxide anion, which is rapidly converted to  $H_2O_2$  and OH. Within 1 minute of reperfusion in experimental systems, 95% of the OH is located in the mitochondria (943). These cyclic bursts of oxygen radicals damage heart mitochondrial membranes, proteins, and DNA.

A high degree of mtDNA damage in chronically ischemic hearts has been confirmed by quantitating the common 5-kbp deletion. Individuals with dilated cardiomyopathy due to chronic ischemia–reperfusion were found to have between 8- and 2200-fold more mtDNA deletion than age-matched controls. Moreover, the levels of the 7436-bp and 10,423-bp deletions went up concurrently with the 5-kbp deletion, and the ischemic hearts showed a coordinate induction of the nuclear OXPHOS genes for ANT1, ANT3, and ATPsyn $\beta$  and the mtDNA genes for MTCYB, MTRNR (12S rRNA), and MTRNR2 (16S rRNA) (448,449). These data suggest that chronic cardiac ischemia and reperfusion result in severe destruction of the cardiac mtDNAs and probably a decline in bioenergetic capacity. This in turn is compensated for by the induction of mitochondrial biogenesis. Elevated mtDNA 5-kbp deletion has also been observed in patients with idiopathic dilated cardiomyopathy (449), and multiple different rearrangements were detected by whole-genome PCR amplification in 18 of 40 dilated cardiomyopathy endomyocardial biopsies (944) and in myocardium (459). Similarly, increased rearrangement and base substitution mutations have been reported in the hearts of children with sudden infant death syndrome (945), and 212 different deletions have been found in the heart of a child with familial dilated cardiomyopathy, versus only five in a control heart. Furthermore, both this patient and a patient with hypertrophic cardiomyopathy were found to have a 12S rRNA A-to-G transition at np 827 that alters a conserved nucleotide (471). Consequently, it is possible that mitochondrial energy depletion may be an important factor in cardiac failure.

Autosomal dominant hypertrophic cardiomyopathy has been linked to mutations in a variety of cardiac contractile protein genes (946–948). However, the pedigrees exhibit variable expressivity, suggesting that other genetic factors may influence the cardiac phenotype. One modifying factor might be mtDNA mutations. Analysis of several hypertrophic cardiomyopathy patients has revealed not only mutations in contractile proteins, but also mutations in the mtDNA, including the tRNA mutations at positions T4314G and A4315G in the MT-TI or at positions A15902G and A15935G in the MT-TT (949).

Mitochondrial defects have been established to cause MM and hypertrophic cardiomyopathy in mice by genetic inactivation of the mouse Ant1 gene (227,905).

These animals also develop multiple mtDNA deletions in their heart mtDNAs associated with increased mitochondrial ROS production (605). Hence, mitochondrial dysfunction can lead directly to cardiomyopathy.

A patient with a null mutation in the ANT1 gene has also been found to have MM together with hypertrophic cardiomyopathy associated with multiple mtDNA deletions (903).

The mouse ANT1 deficiency has been partially ameliorated by transfecting the mouse muscle with the Ant1 cDNA, carried on an adeno-associated virus (AAV) vector. Transduction of the muscle reintroduced functional ANT1 into the muscle, which could transport ATP, resulting in a production of ATP up to 40% of normal. This was accompanied by the restoration of nearly normal muscle histology (950).

### 11.3.3 Idiopathic Sideroblastic Anemia

Idiopathic sideroblastic anemia has also been associated with the appearance of somatic mtDNA mutations in the mtDNA COI gene (951,952). Sideroblastic anemia is characterized by the inadequate formation of heme and the excessive accumulation of iron in erythroblastoid mitochondria. A common finding is anemia associated with ring sideroblasts, which are also seen in Pearson marrow–pancreas syndrome. Sideroblastic anemia is associated with the accumulation of protoporphyrin IX and the deposition of iron in the mitochondria. To make heme, iron must be in the reduced  $Fe^{2+}$  form to be inserted in protoporphyrin IX by ferrochelatase, and the reduction of iron occurs via the ETC. Hence, it has been proposed that sideroblastic anemia may be the result of mitochondrial defects (952). This concept has been supported by the discovery of two novel mtDNA COI missense mutations in patients with sideroblastic anemia. The first patient was found to have a T6721C mutation that changed a highly conserved methionine 273 to a threonine. This mutation was heteroplasmic in the myeloid lineage, but was not present in other tissues of the patient or in the mother or daughter. The second patient was found to have a T6742C mutation that converted the conserved isoleucine 280 to a threonine. This mutation was also heteroplasmic. Hence, it would appear that these somatic mutations arose in the bone marrow and resulted in the physiologic malfunction of the descendant cells (952).

## 11.4 MITOCHONDRIAL ETIOLOGY FOR NEURODEGENERATIVE DISEASES

Evidence is rapidly accumulating that mitochondrial dysfunction lies at the core of many of the neurodegenerative diseases such as Alzheimer disease (AD), Parkinson disease (PD), Huntington disease (HD), amyotrophic lateral sclerosis (ALS), and so on.

## 11.4.1 Alzheimer Disease

**11.4.1.1 The Biology and Genetics of Alzheimer Disease.** Mitochondrial defects have repeatedly been reported for AD brains. AD has been associated with mtDNA haplogroups, aggregates of amyloid  $\beta$  peptide ( $A\beta$ ) have been observed to enter the mitochondrion and inhibit mitochondrial function, the amyloid precursor protein (APP) and the presenilin (PS)  $\gamma$ -secretase which process APP into  $A\beta$  have been associated with the mitochondrion and mitochondrial-endoplasmic protein (ER) complex, and the apolipoprotein E (ApoE) e4 variant associated with late-onset AD correlates has been found to generate a fragment that is imported into the mitochondrion.

AD is the most commonly recognized form of late-onset dementia (953). AD is a progressive neurodegenerative disease resulting in dementia that has been associated with the deposition of  $A\beta$  amyloid peptide plaques and neurofibrillary tangles in the brain (954).

Clinically, AD has been split into early-onset and late-onset forms, divided roughly at age 65. Early-onset AD has been associated with mutations in several autosomal dominant loci, including the APP gene on chromosome 21, presenilin 1 (PS1) on chromosome 14, and PS2 on chromosome 1. APP is processed by “secretase” proteolytic cleavage. A number of APP mutations have been identified which cause the inappropriate processing of APP into  $A\beta_{40}$  and  $A\beta_{42}$  peptides,  $A\beta_{1-40}$  and  $A\beta_{1-42}$ . The  $A\beta$  peptides have been assumed to be toxic, with  $A\beta_{1-42}$  being the more so. The  $A\beta$  peptides have a tendency to aggregate, and it has been found that the toxic forms of  $A\beta$  are oligomers and to a lesser extent filamentous aggregates (955,956). The PSs are required for the secretase processing of APP, with defects in these proteins favoring the accumulation of the  $A\beta$  peptides. Current evidence indicates that PS1 is a component of the  $\beta$ -secretase enzyme complex (957). Multiple pathogenic PS1 missense mutations have been identified that account for the majority of early-onset cases and 2% of the total AD cases (958–960). In addition, two homologous genes encoding  $\beta$ -secretase activity have been cloned, BACE 1 and BACE 2 (961). Tissue-specific transcription levels (962,963) and genetic mapping studies (961) also support a correlation between  $A\beta$  production in AD.

The excessive deposition of  $A\beta$  in AD brains has generated the “amyloid cascade hypothesis” of AD.  $A\beta$  is envisioned as perturbing cellular homeostasis, possibly through altering  $Ca^{2+}$  metabolism or generating toxic ROS. The increased ROS stimulates neurofibrillary tangle formation, which fills and ultimately kills the cell (964). Support for this hypothesis comes from observations that all three autosomal dominant AD genes increase the production of  $A\beta$  peptides. Considerable evidence has implicated aggregates of the  $A\beta$  peptide in increasing cellular calcium permeability, either directly or indirectly through  $Ca^{2+}$  or  $K^+$  channels (965–967).

$A\beta$  might also increase the sensitivity of AD cell mitochondria to oxygen radical generation and  $Ca^{2+}$  toxicity (968). Moreover,  $A\beta$  has been shown to bind  $Zn^{2+}$  and  $Cu^{2+}$  and in that form to aggregate and actually generate ROS, particularly  $H_2O_2$  (969–972). Since increased oxidative damage in AD brains is well documented (973,974), it is very possible that the pathophysiology of amyloid accumulation could be the result of increased neuronal oxidative stress.

Late-onset AD is also genetically heterogeneous, with several loci now implicated in this disease. Although the molecular defects that cause the late-onset, sporadic AD cases have not been determined (975), the inheritance of the ApoE e4 allele has been identified as a major risk factor for developing late-onset AD (975–978). Multiple other loci have been associated with late-onset AD (979–981), although these associations can be controversial. In addition, several groups have associated the interleukin-1 gene with AD (981–986). Another late-onset AD locus on chromosome 10 appears to be related to the insulin degrading enzyme (IDE), which may be involved in the degradation of  $A\beta$  (987,988). A related enzyme, neprilysin, has recently been directly implicated in  $A\beta$  degradation. Suppression of neprilysin in normal rat brain elevates  $A\beta$  deposition (989), and the human neprilysin gene is polymorphic (990).

**11.4.1.2 Mitochondrial Defects in AD.** Multiple studies have implicated mitochondrial OXPHOS defects in both AD. Histologic analysis of AD brains has revealed alterations in mitochondrial morphology in apparently normal dendrites from the superficial cortical layers, which include increased matrix density and paracrystalline inclusions in the intercrystal space (991). Positron emission tomography studies of AD patients have observed decreased glucose transport, suggesting a bioenergetic defect (992), and analysis of brain sections from AD patients has revealed a 30% reduction in PDH activity (993,994) and a 42% reduction in the ADP: $O_2$  ratio, suggesting the partial uncoupling of OXPHOS (995). Chronic inhibition of complex IV in rats by infusion of sodium azide impairs both spatial and nonspatial learning in rats (996), and significant reductions in glucose and glutamine oxidation and calcium accumulation have been reported for AD skin fibroblasts (997). Normal skin fibroblasts treated with the OXPHOS uncoupler carbonyl cyanide *m*-chlorophenylhydrazine show a 10-fold increase in epitopes recognized by antibodies to paired bilateral filaments and a 157-fold increase in the protein detected by the AD-specific monoclonal antibody 50 (998). Finally, ROS have been implicated in AD, both in damaging neurons and in catalyzing the aggregation of the  $A\beta$  peptide (999,1000).

AD patient materials have repeatedly been reported to have partial defects in respiratory complex IV (COX) in both platelet and brain mitochondria (836,1001–1004). These complex IV defects have been proposed to be associated with mtDNA defects, based on their

apparent ability to be transferred from AD patients to cultured cells by fusion of patient platelets to  $p^0$  Ntera/D1 neurons or the neuroblastoma SH-SY5Y. AD platelet cybrids have been reported to have reduced complex IV activity, increased ROS production, and reduced  $Ca^{2+}$  capacity (1003,1005–1015), though the validity of these experiments has been questioned (1016).

Histochemical staining of COX in AD brains revealed marked reduction in activities in the dentate gyrus and the hippocampal subfields (CA1 > CA2 > CA4) (1017). Defects in mitochondrial respiration (995) and in PDH (993,994) have also been reported. Consistent with these biochemical defects, levels for several, but not all, nDNA and mtDNA OXPHOS gene transcripts are reduced in AD brain (1018–1021). This downregulation of specific mitochondrial mRNA levels is paralleled by the downregulation of a variety of genes encoding proteins relevant to AD pathology, as detected by DNA microarray (chip) analysis. Downregulated genes included phosphatases/kinases, cytoskeletal proteins, synaptic proteins, and glutamate and dopamine receptors. By contrast, the cathepsin D mRNA is upregulated in tangle-containing cells (1022).

The potential importance of the mitochondria and oxidative stress in AD has been demonstrated by treating brain synaptosomes and cultured astrocytes with A $\beta$  peptides. Treatment of nucleate- and mitochondria-rich cortical synaptosomes with A $\beta$ ,  $Fe^{2+}$ , or the complex II inhibitor 3-nitropropionic acid reduced glucose and glutamate uptake, reduced mitochondrial  $\Delta\psi$ , increased mitochondrial ROS generation, and stimulated expression of the stress proteins HAP70, HSP60, and GRP78. Moreover, the deleterious effects of these agents were substantially reduced in diet-restricted animals (1023). APP binds to heme oxygenase-2 (HO-2). The heme oxygenases degrade bilirubin to generate an antioxidant and CO. The binding of APP to HO-2 inhibits its antioxidant effects, and this inhibition is greatly accentuated if the APP harbors familial AD mutations (1024,1025).

HO-1 is a stress response protein that degrades heme into CO plus biliverdin. Biliverdin, in turn, is converted to bilirubin, which has free radical scavenging properties. CO is thought to bind and inhibit mitochondria, blocking COX in the ETC and increasing mitochondrial ROS production. The degradation of the heme releases iron, which appears to be taken up by the mitochondria. The excess intramitochondrial iron then stimulates OH production via the Fenton reaction, and the increased mitochondrial oxidative stress is compensated by the induction of MnSOD.

Treatment of cortical astrocytes with A $\beta$  peptides induces HO-1 which results in the sequestration of nonheme iron by the mitochondria and the activation of the mtPTP. These astrocyte effects can be inhibited by concurrent treatment with dexamethasone, which suppresses HO-1 induction, and cyclosporin A, which stabilizes the mtPTP (1026). The induction of HO-1

subsequently results in the induction of MnSOD, and this induction can be blocked by antioxidants including ascorbic acid, melatonin, and resveratrol (1027). These results directly link A $\beta$  peptide toxicity to mitochondrial oxidative stress and the activation of the mtPTP, at least in part through the mediation of HO-1.

While the reason for the specific toxicity of the A $\beta$  peptides for the CA1 layer of the hippocampus is not yet clear, one possibility could lie with the cell- and tissue-specific modulation of the mtPTP in both iron uptake and the induction of apoptosis. Such regulation would require the tissue-specific expression of a protein that interacts with the mtPTP. Expression of the PRAX-1 gene is tissue specific, being expressed at high levels in the CA1 neurons, specifically binding to the mitochondrial benzodiazepine receptor (TSPO) of the mtPTP. PRAX-1 is a 1857-amino acid protein that links two mitochondrial benzodiazepine receptors, and thus mtPTPs, together through their C-terminal peptides. Moreover, PRAX-1 has a long N-terminal end that contains three proline-rich domains, two glutamate-rich domains, an Src homology 3 domain, mitochondrial targeting sequence, and three nuclear targeting signals. Thus PRAX-1 has all of the characteristics that might be expected for a protein coordinating the actions of the mtPTP with other structures in CA1 cells (1028).

A mitochondrial association with AD might also explain the association between the ApoE e4 allele and AD risk, since the presence of the ApoE e4 allele has been associated with increased brain oxidative damage (1029–1031).

A $\beta$  has been reported to enter the mitochondrion through the mitochondrial outer membrane “TOMM” (Translocase of Outer Mitochondrial Membrane) complex, become localized in the mitochondrial cristae, and alter mitochondrial function (1032–1035). A $\beta$  increases mitochondrial membrane viscosity, causing a decrease in ATP/O ratio, reducing ETC activity, increasing ROS production, and facilitating cytochrome c release (1036). Incubation of cultured neurons with A $\beta$  oligomers results in an 89% reduction in mitochondrial membrane potential within 2 hours of exposure, followed by mitochondrial release of cytochrome c and apoptosis initiating factor (AIF) within 8 h (955). Synaptic mitochondria are more sensitive to A $\beta$  mitochondrial toxicity than are neuronal mitochondria, and synaptic mitochondrial dysfunction is an early manifestation in mouse models of AD (1037,1038).

A $\beta$  has been shown to specifically inhibit cytochrome c oxidase (COX or complex IV) (1032,1039). One possible mechanism for this inhibition is that A $\beta$  can bind heme, including the heme-a of COX, creating an A $\beta$ -heme complex, which is also a peroxidase (1040). Chronic exposure of rats to the COX inhibitor  $NaN_3$  results in cognitive deficits and neuronal morphological changes (1041).

A $\beta$  has also been reported to inhibit mitochondrial MnSOD, increasing oxidative stress, and overexpression

of MnSOD is protective of AD (1042). Similarly, A $\beta$  has been reported to inhibit cyclophilin D, a component of the mtPTP (1043). Early stage AD brains also show lipoxidation of the  $\alpha$ -subunit of the ATP synthase, in association with reduced ATP synthase activity (1044). In addition, A $\beta$  perturbs the mtPTP, inhibits OXPHOS complexes III and IV, and also binds and inhibits mitochondrial alcohol dehydrogenase, designated A $\beta$  alcohol dehydrogenase (ABAD) (1033,1035). The interaction between A $\beta$  and ABAD has been associated with mitochondrial dysfunction and dementia, and one hypothesis argues that alteration of ABAD increases mitochondrial aldehyde toxicity (1043,1045–1047).

APP has also been found to be located in the outer mitochondrial membrane (867,1048). Similarly, PS1 has been located in the mitochondrial inner membrane of rat brain and liver (1049). The other components of the presenilin  $\gamma$ -secretase, including nicastrin, APH-1, and PEN-2, have also been found in a high-molecular-weight complex within the mitochondrial inner membrane. Although the import mechanism for these proteins is not fully understood, the nicastrin protein has been found to harbor both ER and mitochondrial N-terminal targeting signals (1050). The processing of APP bound to the mitochondrial outer membrane by mitochondrial  $\gamma$ -secretase would release the APP intracellular domain (AICD) within the mitochondrion (1051). Consistent with the possibility that A $\beta$  enters the mitochondrion, IDE has been discovered to have a mitochondrially directed form generated by initiating translation at an AUG codon 41 amino acids upstream from the canonical IDE peptide start codon. Since the IDE is thought to degrade both cerebral A $\beta$ -peptide and plasma insulin, it could function in mitochondrial A $\beta$  turnover (1052). Mitochondrial A $\beta$  is also turned over within the mitochondrion by presequence protease (1053).

Given that  $\gamma$ -secretase is unique in its ability to cleave peptide bonds within membranes, the PS1 complex might also be involved in processing mitochondrial inner membrane proteins such as those of the respiratory complexes. Hence mutations in the presenilin complex associated with early-onset AD might also cause mitochondrial defects.

PS1 and PS2 have been reported to interact with mitochondrial proteins. They form a complex with the outer mitochondrial membrane protein FKBP38 and Bcl-2 thus modulating mitochondrial mtPTP-mediated apoptosis (1054). PS1 also interacts with Om1/HtrA2, a pro-apoptotic protein stored in the mitochondrial intermembrane space. The C-terminus of PS1 activates the proteolytic activity of Om1/HtrA2, which degrades anti-apoptotic proteins (1055).

The PS1 and PS2 complexes have recently been associated with “mitochondrial-associated membranes” (MAMs). MAMs are thought to be specialized compartments of the endoplasmic reticulum (ER), which connect the ER with the mitochondrion and are important in

lipid and calcium (Ca<sup>++</sup>) metabolism. Altered PS metabolism could thus alter Ca<sup>++</sup> flux into the mitochondrion, initially activating rate-limiting mitochondrial dehydrogenases, then increasing mitochondrial ROS production, and ultimately activating the mtPTP. Activation of the mtPTP would lead to caspase activation and synaptic loss (1056,1057). Thus, the localization of PS1 and 2 in the MAMs is consistent with the observed association between ER stress, Ca<sup>++</sup> dysregulation, and mitochondrial dysfunction in AD (1058,1059).

Late-onset AD cases are commonly associated with the apolipoprotein E gene  $\epsilon$ 4 allele (ApoE  $\epsilon$ 4) (1). This association has been linked to mitochondrial dysfunction by demonstrating that transgenic mice which overexpress ApoE  $\epsilon$ 4 have reduced levels of complexes I, IV, and V (1060). The special neuronal toxicity of ApoE  $\epsilon$ 4 has been proposed to result from ApoE  $\epsilon$ 4's unique ability to undergo an interaction between the N- and C-terminal domains, creating a compact structure. ApoE  $\epsilon$ 4 is then subject to neuron-specific cleavage and the N-terminal cleavage product becomes associated with the mitochondrion and inhibits mitochondrial function (1061,1062).

The ApoE  $\epsilon$ 4 allele is linked to the mitochondrial outer membrane protein import gene, TOMM40. Recently, an association has been observed between a TOMM40 polymorphism and AD, which is independent of the ApoE  $\epsilon$ 4 association, thus further supporting a direct link between mitochondrial function and AD (1063,1064).

A mitochondrial etiology of AD could also explain the near-universal association of A $\beta$  amyloid plaques with AD. At the concentrations found in biologic fluids, A $\beta$ 1-40 and A $\beta$ 1-42 have been proposed to act as antioxidant and antiapoptotic polypeptides, presumably because of their tendency to chelate transition metals, particularly copper. However, when the A $\beta$ s aggregate, they become pro-oxidants, possibly through placing the transition metal in the presence of the redox-active Met 35 (1065–1067). Given this perspective on the A $\beta$  peptides, it could follow that genetic variants which chronically increase mitochondrial ROS production would overwhelm the antioxidant capacity of basal levels of A $\beta$ . To compensate, the brain would increase A $\beta$  production. However, this would eventually lead to excess A $\beta$ , which would then aggregate into a pro-oxidant form (972) and thereby exacerbate the problem. Consistent with this scenario, the brains of late-onset sporadic AD patients have been observed to have increased oxidative damage, increased activated caspase activity (1068,1069), and increased numbers of terminal deoxynucleotidyl transferase biotin-dUTP nick end labeling-(TUNEL) positive cells (1008). Increased mitochondrial ROS would also increase the mtDNA somatic mutation rate and exacerbate mitochondrial oxidative stress, mtPTP activation, and synaptic loss.

AD is associated with neurofibrillary tangles, which are composed of hyperphosphorylated Tau. The N-terminal 20–22 kDa of the Tau protein is enriched in the

synaptosome mitochondria of AD patients and correlates with A $\beta$  multimeric species. Therefore, A $\beta$  interacts with 20–22 kDa N-terminal Tau and the complex may impair mitochondrial function (1070).

Dysfunctional autophagy may also contribute to the decline in mitochondrial function in AD (1071). This may be attributed in part to altered mitochondrial dynamics (fission and fusion) (1072).

Therefore, early-onset AD might also be explained via a mitochondrial pathophysiology. Mutations in the A $\beta$  processing pathway could increase the rate of A $\beta$  production and aggregation, creating an active pro-oxidant that would increase synaptic oxidative stress, damage the mitochondria, and destroy the synapses. Alternatively, mutations in the PS complex could alter the processing of proteins in the mitochondrial inner membrane, resulting in alterations in mitochondrial function and pathology.

**11.4.1.3 mtDNA Mutations in AD.** Genetic evidence that mitochondrial dysfunction may be the underlying cause of AD comes from epidemiologic data that demonstrated that inheriting AD from the mother is 1.7–3.6 times more likely than inheriting the disease from the father (1073,1074). This strong maternal bias in transmission of AD suggests that some mtDNA variants may be risk factors for AD. This concept has been supported by showing that the mitochondrial OXPHOS defects of AD patients can be transferred with the cytoplasm in transmitochondrial cybrids (1075).

Several mtDNA mutations and variants have also been linked to late-onset dementia and AD. One patient with progressive cognitive decline, dementia, deafness, ataxia, and chorea was found to be heteroplasmic for a tRNA<sup>Trp</sup> mutation, MTTW\*DEMCHO5549A. Postmortem analysis of the brain revealed diffuse and moderate neuronal loss in the cortex and basal ganglia with gliosis present throughout the brain. RRFs and COX-negative-staining fibers were evident on skeletal muscle analysis, as were morphologically abnormal mitochondria on electron microscopy of skeletal muscle. A complex I defect was detected in mitochondrial respiration assays. Hence, this tRNA<sup>Trp</sup> mutation demonstrates that mitochondrial defects can cause dementia (748).

Furthermore, analysis of the mtDNAs of late-onset AD patients revealed a significantly increased frequency of the tRNA<sup>Gln</sup> gene polymorphism at np 4336, MTTQ\*ADPD4336G (633,749,751). This A4336G population polymorphism in the tRNA<sup>Gln</sup> gene was found in 3.2% of AD patients but in only 0.4% of controls (633). In one confirmatory study, the np 4336 mutant was found in 6% of AD patients and 0.3% of controls (1076), and in the other this mutation was found in 3.6% of AD but in 0 of 100 controls (749). An Italian study has recently confirmed this association, identifying the A4336G in 2% of AD patients and 0.8% of controls (1077). While the association between the A4336G variant and AD and PD has been confirmed

multiple independent times, the association was not confirmed in two studies (1078,1079).

The MTTQ\*ADPD4336G variant arose in Europe about 8500–17,000 years ago creating a European mtDNA lineage predisposed to neurodegenerative disease, now designated haplogroup H5a (633). Since this was a European-specific variant, it is not surprising that this variant was not found in Japanese AD patients (1080). In the initial survey of AD and PD patient mtDNAs, several additional variants were found, including a missense mutation in ND1 at np 3397, a 16S rRNA mutation, and an insertion in the 12S rRNA gene at np 956 through 965 (633).

An mtDNA A-to-G transition in the ND2 gene at np 5460 variants has also been reported to be associated with AD (634), but was subsequently found to be a polymorphism (635,636,1081). Regional sequencing of the mtDNAs of French Canadian AD patients and controls found one mtDNA lineage that was at increased risk for AD. This lineage harbored the cytochrome b 15,812–amino acid polymorphism (425), which has been shown to be a marker for the Caucasian mtDNA haplogroup J (777,1082). The complete sequence of two other mtDNAs of AD patients were analyzed, one harboring this mtDNA haplotype and another harboring the np 4336 mutation (1083).

Since this first association, multiple studies have shown that certain mtDNA haplogroups either increase or decrease the probability of neurodegenerative disease. Haplogroups U and T have been associated with decreased risk of developing AD in most contexts (425,426,633,1084), though Uk was found to increase AD risk in a brain imaging study (1085).

A mitochondrial role in AD has been further corroborated by the demonstration that in the brains of AD patients who died prior to age 75, the 5-kbp deletion is increased on average 15-fold whereas in the brains of patients who died after age 75, the 5-kbp deletion is present at one-fifth the level of that in control brains (1086). Consistent with this hypothesis, the mtDNAs of AD brains have been found to have 20-fold higher 8-hydroxy-2'-deoxyguanosine (8-OHdG) levels than nDNA, and there is a significant threefold increase in 8-OHdG levels in the mtDNAs of AD parietal cortex relative to controls (479). The sudden drop in the level of mtDNA deletions in older AD brains might be the result of loss of the brain cells containing the most mutated mtDNA through apoptosis. This is consistent with the increased neuronal apoptosis observed in AD brains (1087). However, this elevation of somatic mtDNA rearrangements has not been confirmed in some other studies (1088,1089) one of which only examined patients over age 70 years at which the mutant mtDNAs are lost (1089).

An association between mitochondrial deficiency and AD has been further strengthened by analyzing mtDNA somatic base substitution mutations. Using

protein nucleic acid-clamping PCR, the somatic mtDNA CR T414G mutation in the P<sub>L</sub> mtTFA binding site was detected in 65% of all AD brains and in 57% of Down syndrome (DS) patients which developed dementia (Down syndrome and dementia (DSAD)) but not in any control brains. Moreover, the level of somatic mtDNA CR mutations in AD brains is increased by 63% overall, with the elevation of somatic mtDNA CR mutations in AD patients over 80 years being 120%. Furthermore, in the AD and DSAD brains, the somatic mtDNA mutations preferentially occur within the known mtDNA transcription and replication regulatory elements, whereas very few of the mtDNA CR mutations found in the control brains occur in functional elements. The increased mtDNA somatic mutation rate is systemic, since analysis of brain and blood mtDNAs from autopsy samples of the same individuals revealed that the somatic mtDNA mutations were elevated in both tissues. Furthermore, in some cases, the same somatic mtDNA control region mutation was found at high levels in brain and blood tissues of the same individual indicating that the mutation must have arisen early in development. Elevated somatic mtDNA mutations were also observed in lymphoblastoid cell lines of AD and DSAD derived cell line. Consistent with the accumulation of somatic mutations in association with dementia, the quantification of the ratio of brain ND6:ND2 mRNA levels revealed approximately a 50% reduction in the ND6 levels in AD, DS, and DSAD brains relative to controls. Moreover, the mtDNA:nDNA ratio was decreased in AD and DSAD brains relative to age matched controls, even though the mtDNA:nDNA ratio declined with age in normal brains. Interestingly, the mtDNA:nDNA ratio was increased in DS brains, suggesting a compensatory upregulation of mitochondrial biogenesis prior to the onset of dementia (1090,1091).

These data suggest that the accumulation of somatic mtDNA CR mutations in AD brains that damage key mtDNA regulatory elements may be a central feature in the etiology of the disease. The accumulation of these mutations with age would result in a progressive decline in mitochondrial energy production and an associated increase in mitochondrial ROS production. The increased ROS would ultimately lead to the activation of the mtPTP and the loss of neuronal synapses through mitochondrial-induced cytochrome c release and caspase activation.

By this logic, individuals harboring mtDNAs that generate tightly coupled mitochondria would experience chronically increased ROS production on a high-calorie diet. This would increase the probability of mtDNA CR mutations and thus the probability of developing AD. By contrast, individuals who harbor mtDNAs with uncoupling polymorphisms, such as haplogroup J, would have reduced mitochondrial ROS and be less prone to somatic mtDNA CR mutations and AD. Population studies have confirmed these predictions (425).

### 11.4.2 Parkinson Disease

About 20% of AD patient brains also show the neuro-pathologic features of PD (AD-PD). Idiopathic PD is a progressive movement disorder characterized by bradykinesia, rigidity, and tremor associated with the death of dopaminergic neurons in the substantia nigra. Clinical symptoms generally become apparent when ~80% of the dopaminergic neurons are lost. Neuropathologically, PD patients' neurons contain characteristic cellular inclusions known as Lewy bodies composed of  $\alpha$ -synuclein and ubiquitin. (1092–1094). The link between AD and PD is also supported by inclusion body myositis, which is associated with intermyofiber accumulations of A $\beta$ . Parkin is expressed in the brain, skeletal muscle, and other tissues, and muscle and cells lacking parkin are more sensitive to intracellular A $\beta$  toxicity. Increased levels of parkin are protective of both mitochondrial toxins and A $\beta$  (1095).

Genetically, PD is heterogeneous (1096) and classical twin studies have been unsuccessful at defining the extent of the hereditary component (1097). The first clear evidence that mitochondrial dysfunction might contribute to PD came from investigating the induction of PD by a contaminant of illicitly synthesized meperidine, MPTP (1098). MPTP is oxidized by monoamine oxidase B into its active form, 1-methyl-4-phenylpyridinium (MPP). MPP is actively taken up by the dopaminergic neurons of the substantia nigra through the dopamine transporter and electrostatically attracted into the mitochondrial matrix, like other lipophilic cationic compounds (1093,1099,1100). The selective concentration of MPP in dopaminergic neurons and their mitochondria increases the mitochondrial matrix concentration of MPP several hundredfold, into the millimolar range. At this concentration, MPP binds to complex I and inhibits respiration by NADH-linked substrates. The inhibition of complex I occurs between the highest potential iron-sulfur cluster and CoQ, the same site that binds rotenone (1093,1099,1100). The inhibition of complex I by MPP is thought to increase the complex I production of ROS, which is supported by the fact that MnSOD-deficient mice are more sensitive to MPTP (1101).

Chronic rotenone exposure has also been shown to induce parkinsonism in rats and to reproduce the anatomic, neuropathologic, and behavioral changes seen in PD (1102,1103). This is also associated with the induction of complex I ROS production, which can be blocked by treatment with the antioxidant  $\alpha$ -tocopherol (vitamin E) (1104). Finally, annonacin, a product of the tropical plant soursop, whose leaves are used to make a tea in Guadeloupe in the French West Indies, is a complex I inhibitor and is associated with an atypical form of PD (1105). Hence, environmental inhibition of mitochondrial complex I in the brain would appear to be one important cause of PD (1102).

The analysis of mitochondrial OXPHOS enzymes in the brain, blood, and muscle cells have also frequently

revealed complex I deficiencies in PD patients. Initial studies of the substantia nigra of autopsy patients revealed a 30–40% reduction in complex I activity (1106–1108). Skeletal muscle mitochondrial from PD patients has also been found to have mitochondrial complex I defects and in some cases other OXPHOS defects as well (1109–1111). Complex I deficiencies have also been reported in the blood platelets and isolated mitochondria from PD patients (1093,1112–1115). That some of the mitochondrial defects found in PD might have an mtDNA etiology has been suggested by cybrid experiments in which the patient's platelets are fused to cells that lack mtDNA and the cybrids biochemically characterized (1075,1116,1117). Hence, considerable data have accumulated indicating that PD patients harbor OXPHOS defects.

While the above studies implicated mitochondrial defects in PD, the fact that about 10% of PD cases showed a classical Mendelian mode of inheritance was originally taken as evidence that the mitochondrial defects were secondary to some other brain-specific nDNA genetic defect. This perspective has changed radically as the various nDNA PD genes have been cloned and their functions assessed. In the great majority of cases, the mutant nDNA gene has been found to affect mitochondrial function and integrity.

Both autosomal dominant and autosomal recessive nDNA gene mutations have been identified. The two dominant PD genes encode  $\alpha$ -synuclein (PARK1) and LRRK2 (PARK8). The  $\alpha$ -synuclein gene was the first Mendelian PD gene to be cloned (1118) and its deficiency shown to be associated with mitochondrial function (1119–1121). Inactivation of  $\alpha$ -synuclein results in a 28% reduction in the molar concentration of brain cardiolipin, reduction in the polyunsaturated side chain levels of mitochondrial cardiolipin, alteration in the mitochondrial inner membrane fluidity, and reduction in the electron flux rate between the mitochondrial respiratory complexes (1122). Recently,  $\alpha$ -synuclein has been shown to heal the distortions that arise in lipid bilayers when they are subjected to a high degree of bending, a common characteristic of mitochondrial inner and outer membranes. Since the disruption of the lipid bilayer creates the substrate for the fusion of two membranes, increased  $\alpha$ -synuclein decreases mitochondrial fission (1123).

The second autosomal dominant locus encodes the Leucine-rich repeat kinase 2 (LRRK2). Mutations in this gene account for about 1–2% of spontaneous cases. LRRK2 is a serine-threonine protein kinase as well as a GTPase, and the most common PD mutation causes a G2019S codon change. Patient fibroblasts harboring a mutant LRRK2 have reduced mitochondrial membrane potential; ATP production using complexes I, II, or IV-lined substrates; and increased mitochondrial elongation and interconnectivity (1124). Since the G2019S mutation increases the kinase activity and the  $\alpha$ -synuclein in Lewy Bodies is phosphorylated, it has also been

proposed that LRRK2 might also be the  $\alpha$ -synuclein kinase (1125).

Among the recessive Mendelian PD genes, four have been linked to the mitochondrion. The Omi/HtrA2 protein gene (PARK13) is a serine-protease which resides in the mitochondrial intermembrane space. When released from damaged mitochondria it can activate the caspase cascade of apoptosis. Its serine-protease activity is activated by phosphorylation by the PD-associated PINK1 kinase (352).

DJ-1 (PARK7) plays a role in protecting mitochondria from oxidative stress. ROS converts the DJ-1 cysteine 106 to sulfinic acid and this protects neurons from cell death (136) (1126). DJ-1 is associated with complex I defects, increased mitochondrial ROS production, reduced mitochondrial membrane potential, and altered mitochondrial morphology including reduced mitochondrial branching and disintegration of the mitochondrial network but with increased mitochondrial mass. These effects are associated with decreased autophagy levels and reduced lysosomal activity (1127,1128). The *Drosophila* homolog of DJ-1 is predominantly localized to the mitochondrion, and its genetic inactivation results in reduced locomotor function and increased sensitivity to paraquat-induced oxidative stress. The loss of the DJ-1 homolog in *Drosophila* also reduces mitochondrial ATP production in association with uncoupled mitochondria (1129,1130).

Studies of DJ-1-deficient mice have revealed that the reason that the SNc dopaminergic neurons die but the adjacent ventral tegmental neurons do not is due to differential mitochondrial oxidative stress in the SNc neurons. During repetitive pace-making neuronal discharge,  $\text{Ca}^{++}$  enters the SNc neurons through L-type channels. This results in oscillating mitochondrial oxidative stress as the mitochondria drive OXPHOS to maintain the membrane potential decreased by the uptake of cytosolic  $\text{Ca}^{++}$  into the mitochondrion. The increased mitochondrial ROS production is partially mitigated by a 20–30 mV decrease in the mitochondrial membrane potential achieved by increased expression of the UCPs, UCP4 and UCP5. DJ-1 is a redox sensitive participant in a signaling cascade activated by mitochondrial superoxide which helps to sustain the expression of UCP4 and UCP5. Therefore, loss of DJ-1 reduces the uncoupler protein levels, increases the SNc neuron oxidative stress, and predisposes these neurons to death. Since the ventral tegmental neurons do not undergo the  $\text{Ca}^{++}$  oscillations and concomitant oxidative stress, they are more resistant to the mitochondrial oxidative stress toxicity (1131).

The recessive parkin (PARK2) (1132) and PTEN-induced kinase 1 (PINK1, PARK6) (1133) protein genes are also related to the mitochondrion, since they have been found to be central components of the mitochondrial quality control system mediating the turnover of defective mitochondria. PINK1 is targeted to normal mitochondria but is cleaved and degraded. However,

in damaged mitochondria, it remains intact in the outer mitochondrial membrane (347) where it phosphorylates the cytosolic protein parkin. The phosphorylated parkin is attracted to the mitochondrion (348), and since it is an E3 ubiquitin ligase it ubiquitinates mitofusins 1 and 2 (349). The ubiquitinated mitofusins attract the adaptor protein p62/SQSTM1 (351) which recruits the mitophagy apparatus including microtubule-associated protein 1 light chain 3 (LC3) protein and the Atg autophagy proteins to engulf the mitochondria in an autophagosome which subsequently fuses with the lysosome to degrade the mitochondria. Mutations in PINK1, parkin, and the lysosomal ATPase, ATP13A2 (PARK9) can all inhibit this process (353). Since PINK1 is inactivated in normal mitochondria, but remains active in mitochondria with a reduced membrane potential, this system selectively removes defective mitochondria (352–354).

Mitochondria are continually undergoing fusion and fission within the cell (339). This permits the sharing of mtDNA gene products and thus the complementation in *trans* of mutant mtDNAs within the cell (341,344). However, as the load of mutated mtDNAs increases in the cell, the overall energetic capacity declines. At this point, it becomes essential to reduce the proportion of mutant mtDNAs. mtDNAs are packaged in nucleoids which appear to be composed of a clone of one type of mtDNA. Therefore, nucleoids with mutant mtDNAs need to be isolated in a surrounding mitochondrial membrane vesicle so that their defect can be recognized by PINK1 and removed by parkin and ATP13A2. This compartmentalization of mutant mtDNA nucleoids is accomplished by mitochondrial fission. Therefore, mitochondrial fission is essential for PINK1 and parkin activation (1134).

Since overexpression of  $\alpha$ -synuclein inhibits fission, overexpression or triplication of the  $\alpha$ -synuclein would result in long mitochondria which would inhibit the separation and removal of mutant mtDNAs. This effect can be only be compensated by the overexpression of PINK1, parkin, or DJ-1 (1123).

Thus, many of the chromosomal PD genes are part of an integrated pathway for maintaining the integrity of the mitochondria. This includes the mitochondrial fusion and fission system to isolate mutant nucleoids, the decline of OXPHOS and the mitochondrial membrane potential of the mitochondrial fragments harboring mutant mitochondria, the stabilization of PINK1 in the fragmented-mtDNA mutant mitochondria, the recruitment of parkin to damaged mitochondria, and the degradation of the defected mitochondrion and its mtDNA through mitophagy.

Consistent with this model, overexpression of the PINK1-parkin pathway in cultured cells harboring a heteroplasmic mtDNA mutation has been found to reduce the percentage of mutant mtDNAs. In cells heteroplasmic for a mtDNA complex IV COI, gene mutations (COXICA65) were studied at a high percentage mutant, the mitochondrial membrane potential declined to 45%

of normal and the PINK1-parkin pathway was activated to reduce the mutant mtDNA levels. By contrast, a cell line heteroplasmic for a cytochrome b mutation (Cytb3.0) with a 63% or normal mitochondrial membrane potential the PINK1-parkin mitophagy pathway was not activated and the mutant mtDNA load was not reduced. This suggests that the critical membrane potential threshold must be about 50% of normal. The rate and extent of removal of the COI mutant mtDNAs can be accelerated by inhibiting mitochondrial fusion with vMIA or blocking the ATP synthase from sustaining the inner membrane potential by hydrolyzing ATP (1134).

The demonstration that nDNA-encoded PD loci are involved in maintaining mtDNA and mitochondrial integrity implicate the accumulation of mtDNA damage and mutations in PD. Direct evidence that mtDNA mutations can influence the predisposition to PD has come from the report that a pedigree showing the maternal transmission of PD was found to harbor the common LHON pathogenic mutation MTND4\**LHON11778A* (1135), and the MTND6\**LDYT14459A* mutation has been repeatedly linked to generalized dystonia (537,538). Furthermore, the 12S rRNA np 1555 (*MTRNR1\*DEAF1555G*) mutation was observed in a family with sensorineural hearing loss, tremor, and Parkinsonism (1136). The mtDNA tRNAGln np 4336 (*MTTQ\*ADPD4336C*) variant has been found 5.3% of late-onset in PD and 6.8% in AD + PD versus 0.4% in controls (633) and in other studies this mutation has been found in 8.7% of PD cases but in 0 of 100 controls (749). Consistent with an mtDNA role in PD, haplogroup H has been associated with increased risk, and haplogroups J and Uk with decreased risk, for developing PD (424,1137,1138).

The accumulation of somatic mtDNA mutations has also been demonstrated in PD. The common 5 kb mtDNA deletion accumulates with age in many tissues, but it reaches the highest levels in the cerebral cortex and the basal ganglion of the brain, the tissues affected by AD and PD (452,453). Deletions in the mtDNA of dopaminergic neurons have also been observed in the SNc of patients and aged-controls. The mtDNA deletions have also been associated with neuronal OXPHOS enzyme defects by histochemical staining (1139,1140). Base substitution mutations in the mtDNA control region have also been found to be elevated in PD brains (1141).

The increase in somatic mtDNA mutation would appear to be systemic as has been found in AD. Analysis of blood platelet mitochondria has revealed mitochondrial complex I and complex IV defects (1112) and when platelets are fused to cultured human neuroblastoma cells lacking mtDNA ( $\rho^0$ ) mitochondrial defects are introduced. The resulting trans-mitochondrial cybrids have been found to harbor OXPHOS complex I defects, increased mitochondrial ROS production, altered mitochondrial  $\text{Ca}^{++}$  regulation, altered mitochondrial fission–fusion dynamics, Lewy Bodies, and altered neurological signaling (1013,1116,1117,1142–1145).

### 11.4.3 Huntington Disease

Studies on HD have implicated mitochondrial dysfunction in its etiology as well (412,1146–1148). HD is inherited as an autosomal dominant mutation resulting from the expansion of a CAG repeat in the first exon in the IT15 gene creating an extended polyglutamine (polyQ) stretch of amino acids of the huntingtin protein (Htt). Expansion of more than 36 repeats results in predilection to symptoms which is associated with the appearance of nuclear aggregates of mutant Htt complexed with ubiquitin (1149). The Htt protein is ubiquitously expressed, but the neurological symptoms correlate with the loss of  $\gamma$ -aminobutyric acid (GABA) medium spiny neurons of the striatum. The Htt contains 36 HEAT helix-loop-helix domains that mediate its interaction with multiple proteins involved in gene expression, endocytosis, vesicle trafficking, intracellular signaling, and metabolism. The age of onset can vary from 30 to 50 years and once initiated the disease progresses over the next 12–50 years leading to death (1146). The age of onset correlated with the length of the polyQ expansion, with accounts for about 73% of the variance in motor functions (1150).

While the precise function of the Htt protein remains unknown, considerable evidence has accumulated indicating that HD patients have a major defect in energy metabolism. Patients have elevated lactate in their basal ganglia and occipital cortex; reduced brain ATP; reduced phosphocreatine to phosphate ratios as assessed by  $^{31}\text{P}$ -NMR spectroscopy; reduced  $^{18}\text{F}$ -2-deoxyglucose ( $^{18}\text{F}$ -2-DOG) uptake in HD cortex and striatum by PET, increased sensitivity of the mtPTP to  $\text{Ca}^{++}$  activation possibly resulting for mutant Htt interaction with the ER InsP3R1  $\text{Ca}^{++}$  channel; reductions in OXPHOS complexes II and III in the caudate and putamen; and a 90% reduction in mitochondrial aconitase in the caudate, a 70% reduction in the putamen, and a 50% reduction in the cortex (1146,1151). HD patients also show a reduced anaerobic threshold during exercise stress tests (1152) and treatment of rodents with the mitochondrial complex I (SDH) inhibitor 3-nitropropionic acid (3-NP) mimics the features of the diseases (1153). Sensitization of the mtPTP and inactivation of the complexes II and III and mitochondrial aconitase suggest that mutant Htt increases mitochondrial oxidative stress since the mtPTP is sensitized by ROS (33,1154,1155) and complexes II and III and mitochondrial aconitase all incorporate iron-sulfur centers which are readily inactivated by ROS (460,1156–1158). This conclusion is supported by the demonstration that HD patients have increased levels of the lipid peroxidation product 4-hydroxy-2-nonenal (4-HNE) as do the striatum of the R6/2 mouse model of HD and treatment of R6/2 striatal neurons of R6/2 mice with the antioxidant nordihydroguaiaretic acid (NDGA) restored mitochondrial structure and function (1159). The importance of energy metabolism in HD has

been confirmed in a *Drosophila* in which the Htt mutant protein, Httex1pQ93, was expressed in glial and neuronal cells. When Httex1pQ93 was expressed in glia, the motor dysfunction of the flies could be improved and life span extended by the systemic expression of *Drosophila* UCP (DmUCP5). This protection was also obtained when human UCP2 was expressed in glial cells alone. However, DmUCP5 overexpression failed to protect the flies when Httex1pQ93 was expressed in neurons. By contrast when *Drosophila* MnSOD and mitochondrially targeted catalase (mCAT) were expressed in flies they showed protection for expression of Httex1pQ93 in neurons but not in glia. *Drosophila* in which Httex1pQ93 was overexpressed in glia could also be rescued by the overexpression of the *Drosophila* glucose transporter (DmGluT1) (1149). These data confirm that the motor symptoms in this *Drosophila* model system of HD are the results of defects in energy metabolism, primarily mediated by increased mitochondrial oxidative stress in neurons but by energy deficiency in the more glycolytic glia.

Abberations in mitochondrial morphology have also been documented in HD and linked to excess mitochondrial fission over fusion leading to mitochondrial fragmentation and the loss of mitochondrial cristae organization. HeLa cells transformed with an N-terminal fragment of Htt containing 17, 28, 74, and 138 polyQ were examined for mitochondrial function and mitochondrial morphology. In cells harboring the Htt fragment with 74 polyQ, the mitochondria were observed to be clustered around the nucleus and were of smaller length. Cells expressing Htt fragments with 74 and 138 repeats were found to be sensitized to oxidative stress (25 mM  $\text{H}_2\text{O}_2$ )-induced mitochondrial fragmentation with highly disorganized cristae. The 74Q Htt cells had 30% less ATP than cells expressing 28Q Htt. Cells with the 74 polyQ Htt had reduced mitochondrial movement, fusion, and ATP levels which could be compensated by addition of a dominant negative Drp-1 or normal Mfn2 protein. In a *Caenorhabditis elegans* expressing Htt28Q and Htt74Q in muscle, the longer repeat lengths were associated with reduced worm mobility which could be offset by knockdown of Drp-1 (1160). The relevance of these in vitro to HD patients was demonstrated by the analysis of mitochondrial fission and fusion, mRNA, and protein levels in HD brains versus control brains. This revealed that the mRNA levels for the mitochondrial fission proteins Drp1 and Fis1 were increased while those of the mitochondrial fusion proteins, Mfn1, Mfn2, and Opa1 were decreased. Cyclophilin D (CypD) was upregulated in HD brains and the level of CypD mRNA increased as the disease progressed. Drp1 was increased by 2.8- to 10.9-fold and Fis1 6.9- to 36.2-fold while Opa1 mRNA was reduced by 2.6- to 4.3-fold, Mfn1 2.5- to 4.0-fold while Mfn2 mRNA was reduced 3.4- to 50-fold. CypD mRNA was increased by 9.8- to 50-fold. These changes were reflected in relative levels of protein. OXPHOS mRNAs were increased about twofold along

with increased levels of cytochrome b and COI in HD brains. Mutant Htt oligomers were found to be associated with both the nucleus and the mitochondria (1161).

The anatomical relevance of this to HD mitochondrial morphology was confirmed by analysis of the mitochondrial morphology of lymphoblastoid cell lines derived from HD patients. Lymphoblastoid lines heterozygous for a 48Q allele had striking abnormalities in mitochondrial ultrastructure including mitochondrial fragmentation and clustering with deranged mitochondrial cristae. The prop-fission protein, Drp-1 is normally phosphorylated and inactive in mitochondrial fission. However, when dephosphorylated by calcineurin, Drp-1 binds to the mitochondrion and initiated fission. The calcineurin phosphatase is activated by  $\text{Ca}^{++}$  which has been observed to be elevated in HD tissues. Calcineurin activity was also found to be elevated in cells with 111Q Htt in association with increased releasable ER stores of  $\text{Ca}^{++}$ . Mitochondrial fragmentation could be corrected by increased expression of OpaI, Mfn1, or dominant-negative Drp-1. HD lymphoblasts as well as striatal neurons from the YAC128 mouse model of HD were more sensitive to intrinsic mitochondrial cell death initiated by staurosporine,  $\text{H}_2\text{O}_2$ , and etoposide. This was associated with a greater tendency of the polyQ cell mitochondria to release cytochrome c which correlates with the disruption of the OpaI oligomers that are responsible for maintaining the cristae junctions and is consistent with cristae remodeling being activated by Drp-1. Calcineurin inhibition by FK506 prevented translocation of Drp-1 to the mitochondrion and protected polyQ cells from cell death. Expression of OpaI protected the mitochondrial cristae from disruption by pro-apoptotic stimuli (1162).

These observations lead to a scenario of how mitochondrial functional morphology might be modulated in HD. Mutant Htt interacts with the plasma membrane  $\text{Ca}^{++}$  channels VGCC and NMDAR to increase  $\text{Ca}^{++}$  influx into the cell and with the InsP3R1 receptors in the ER to release its  $\text{Ca}^{++}$  stores (1146,1151). The increased cytosolic  $\text{Ca}^{++}$  then activates the calcineurin phosphatase to dephosphorylate phospho-Drp-1. The dephosphorylated Drp-1 then migrates to the mitochondrion where it initiates fragmentation. This destabilized the OpaI cristae junction structures and increases the sensitivity of the mitochondria to stress-induced cytochrome c release thus increasing the predilection of the striatal neurons to undergo apoptosis (1163). Hence, according to this model, the tendency of mutant Htt causes mitochondrial dysfunction through altered mitochondrial dynamics.

Another model of how the polyQ expansions of mutant Htt impinged on mitochondrial function is through transcriptional regulation of the nDNA-encoded mitochondrial genes (1146). This follows from the discovery that the mutant Htt protein interferes with the expression of PGC-1 $\alpha$ , the nDNA-encoded mitochondrial gene transcriptional coactivator. Initially, it was observed that HD model R6/2 mice were cold intolerant

and since adaptation to cold stress in the mouse is mediated by PGC-1 $\alpha$  induction of UCP1 in brown fat, this implied a defect in PGC-1 $\alpha$ . This was confirmed by showing a reduction in PGC-1 $\alpha$ mRNA as well as the reduction in the mRNAs of multiple mitochondrial PGC-1 $\alpha$  target genes. It was corroborated by demonstrating reduced respiration on site I substrates and reduced membrane potential, defects that could be ameliorated by overexpression of PGC-1 $\alpha$  (1164). Analysis of muscle of HD patients confirmed the systemic reduction in PGC-1 $\alpha$  and revealed reduction of PGC-1 $\beta$ , oxygen consumption, and oxidative fibers. In HD myoblasts, knockdown of mutant Htt increased PGC-1 $\alpha$  expression. Reduction in the muscle expression of PGC-1 $\alpha$  and its target genes was also confirmed in HD transgenic mice (1165). In parallel studies, PGC-1 $\alpha$  expression was found to be reduced 30% in the caudate of HD patients, though not in the hippocampus or cerebellum. Moreover, expression was reduced 5.6-fold in the medium spiny neurons but increased 47-fold in the interneurons. In striatal neuronal cultures of STHdh<sup>Q111</sup> mice, cAMP, ATP, cytochrome c, and COXIV levels were decreased and PGC-1 $\alpha$  mRNA was reduced 10-fold. These effects could be partially reversed with the cAMP analog 8-bromo-cAMP, PGC-1 $\alpha$ , or by increased levels of TAF4 plus CREB. In R6/2 mouse brains, PGC-1 $\alpha$  mRNA was reduced. Moreover, mutant Htt was found associated with the CREB/TAF4 complex on the PGC-1 $\alpha$  promoter, which contrasts with normal Htt's association with the dopamine D2 receptor gene. Striatal necrosis associated with mutant Htt expression could also be ameliorated by Lentivirus transduction of PGC-1 $\alpha$  (1166). Mutant Htt has been found to interact with the cAMP responsive element (CRE) binding protein (CREB) through interaction with the CREB-binding protein (CBP) and with the TAT box-binding protein (TBP)-associated factor TAF4/TAFII130. Since this complex regulates the expression of PGC-1 $\alpha$ , this could be the mechanism for inhibition of PGC-1 $\alpha$  by mutant Htt (1151,1167–1169).

Transglutaminase 2 (TG2), which is the predominant transglutaminase in the brain, has also been proposed to play an important role in the pathophysiology of HD. TG2 has multiple functions, though the primary enzymatic function is the  $\text{Ca}^{++}$ -activated transglutaminase reaction in which a peptide-bound glutamine forms a thioester intermediate with a TG2 cysteine which then reacts with a suitable nucleophile such as a lysine within another polypeptide to form glutamate  $\epsilon$ ( $\gamma$ -glutamyl) lysine cross-links. TG2 can also mediate the reaction of polyamines to proteins. TG2 is important in forming cross-links for extracellular matrix proteins but has also been found to translocate to the nucleus under certain conditions. In the absence of  $\text{Ca}^{++}$  TG2 becomes a GTPase (1170).

While TG2 levels do not increase in the presence of mutant Htt, the presence of increased polyQ tracks stimulates TG2 cross-linking activity. Furthermore,

increased cytosolic  $\text{Ca}^{++}$ , in part due to the mHtt activation of NMDA receptors should stimulate the activity of TG2. Genetic inactivation of TG2 in R6/2 mice provides substantial protection against cortical and striatal brain neuron death, a 12% increased in life span, and a significant increase in motor activity. Interestingly, reduction of TG2 increases the extent of neuronal internuclear inclusions supporting the idea that these aggregates are protective rather than deleterious (1171).

In striatal neurons cultured from HdhQ111 knock-in mice, STHdh<sup>Q111</sup> cells, expression array studies have revealed that 461 genes are dysregulated, 289 upregulated, and 172 downregulated. The TG2 protein has two nuclear localization signals and treatment of STHdh<sup>Q111</sup> cells with the TG2 inhibitor peptide inhibitor, Z-QVPL (ZDON) returned 42% of the dysregulated genes toward normal suggesting that TG2 has a role in transcriptional regulation. Direct analysis of the PGC-1 $\alpha$  and cytc mRNAs in mutant cells confirmed that PGC-1 $\alpha$  mRNA was reduced 80% and that cytc mRNA was reduced 40% but inhibition of TG2 increased PGC-1 $\alpha$  mRNA 3- to 4.5-fold and cytc mRNA 3-fold. Transformation of the cells with a cytc promoter luciferase reporter construct confirmed that mHtt decreased transcription and that inhibition of TG2 increased promoter activity 250%. Using chromatin immunoprecipitation (ChIP) it was found that STHdh<sup>Q111</sup> cells had 10X more TG2 at the cytc promoter than did control STHdh<sup>Q7</sup> cells. Similarly, TG2 was 5X increased within the PGC-1 $\alpha$  gene at the boundary region of intron 2 and exon 3, and the TG2 inhibitor, ZDON, reduced the TG2 occupancy of this site back to that of STHdh<sup>Q7</sup> cells. Consistent with the inhibition of PGC-1 $\alpha$ , the total mitochondrial mass, citrate synthetase activity, ND6 protein level, and mitochondrial membrane potential were all decreased in STHdh<sup>Q111</sup> cells and these reductions were partially restored by treating the cells with ZDON. Another mRNA that was downregulated in the STHdh<sup>Q111</sup> cells was the HSP40 chaperone family member DNAJB10 which was also normalized by ZDON. While HDAC inhibitors have been shown to partially reverse the transcriptional inhibition associated with HD including the upregulation of PGC-1 $\alpha$ , TG2 regulation proved to be independent of the HDACs, though a clear interaction has been seen between TG3 and histone 3 (H3) (1172,1173).

The N-terminal amino acid tails of histones are positively charged and bind to the negatively charged sugar-phosphate backbone of DNA shutting down transcription. Modification of the histone tails by phosphorylation using ATP, acetylation using acetyl-CoA, of methylation by S-adenosylmethionine (SAM), all of which are reliant on energy flux through the mitochondria, results in the repulsion of the tails and the opening of the chromatin to transcription; thus when there is sufficient energy to support biogenesis the epigenome is modified and turns on nDNA gene expression (13). The observation that TG2 regulates transcription has

led to the hypothesis that TG2 becomes activated by mHtt which modulates particular transcriptional circuits including those of transcription factors that incorporate glutamine-rich activation domains including Sp1, CREB, and NRF-1. These, in turn, regulate the transcription of nDNA-encoded mitochondrial genes. This effect seems to be enhanced by the polyQ expansion of mutant Htt. Activated TG2 reacts with glutamines 5 and 19 in H3 and perhaps glutamine 22 in histone 2B to attach a polyamine. The increased positive charge increases the affinity of the histone tails to the DNA thus inhibiting transcription of the target genes, one of which is PGC-1 $\alpha$ . This, in turn, downregulates mitochondrial biogenesis and probably the distribution of calorie flow from glycolysis and fatty acid oxidation into the mitochondrion. Reduced mitochondrial energy flux renders the GABAergic medium spiny neurons less resistant to stress ultimately leading to their death (1173).

Consistent with an important role of mitochondrial genes in HD, in a German cohort mtDNA haplogroups were found to contribute to the age of onset of HD. Patients harboring mtDNA haplogroup H, as assessed by the COI SNP nt C7028T, were found to have a significantly lower age of onset and higher ATP levels in PHA-stimulated CD4<sup>+</sup> cells (1174). HD patient age of onset was also associated with a polymorphism in intron 2 of PGC-1 $\alpha$  (1175) as well as polymorphisms in nuclear respiratory factor 1 gene (NRF-1) and in mtDNA transcription factor A gene (TFAM) (1150). The combination of the mtDNA haplogroup H polymorphism plus the PPARGC1A, NRF1, and TFAM polymorphisms have been proposed to account for about 4.8% of the age of onset variance (1150). Given that mtDNA and nDNA mitochondrial genetic variation can modulate the age of onset of HD, it follows that the delayed onset and progressive course of the disease should be associated with an elevated mtDNA somatic mutation rate. Analysis of the level of the common mtDNA 5 kb deletion in HD patient's cerebral cortex has confirmed that somatic mtDNA mutations are indeed elevated (1176).

The importance of somatic mtDNA mutations in HD have been confirmed by generating cybrids via fusion of patient blood platelets from HD patients to cultured human cells which lack mtDNA ( $\rho^0$ ). The resulting cybrids have been found to have defects in glycolytic and mitochondrial function (1177). Since the inherited defect in HD is a nuclear trinucleotide repeat mutation and platelets lack nDNA, the only way that these observations can be connected is if the nDNA HD mutation caused secondary mutations in the blood cell mtDNAs which were then transferred to somatic cell cybrids.

Since in AD somatic mtDNA mutations are elevated in both brain and blood cells (1091) and somatic mtDNA mutations are elevated in AD, PD, and HD, it seems likely that the pathophysiology and genetics of all three of these diseases has the same basis of mitochondrial dysfunction.

### 11.4.4 Amyotrophic Lateral Sclerosis

ALS is a fatal neurodegenerative disease associated with upper and lower motor neuron dysfunction. It typically manifests between ages 50 and 60 years, resulting in paralysis and death within 2–5 years. Neuropathological studies reveal pallor of the corticospinal tract due to loss of motor neurons and the presence of ubiquitin-positive inclusion within the surviving motor neurons and the presence of TDP-43 positive aggregates containing the TAR-DNA binding protein (TARDBP or TDP-43). Approximately 5% of ALS is familial and of these, about 15–20% of the cases are caused by mutations in the Cu/Zn superoxide dismutase (Cu/ZnSOD) gene, *Sod1*. A significant proportion of the remaining familial cases are the result of mutations in the TARDBP, *FUS* (fused in sarcoma, a RNA-binding protein), *OPTN* (optineun), vesicle-associated membrane protein B, valosin-containing protein (VCP) gene, and C9ORF72 genes (1178–1182).

The most extensive studies on the pathophysiology of ALS have been conducted on ALS-associated mutations in the *SOD1* gene. Transgenic mice that express a human mutant Cu/ZnSOD develop motor neuron disease associated with vacuolated mitochondria containing high concentrations of Cu/ZnSOD (1183). The mutant Cu/ZnSOD mice also accumulate 8-OHdG in cytoplasmic granules, possibly representing mtDNA nucleoids (1184), and in cultured neuroblastoma cells, the toxicity of a mutant Cu/ZnSOD can be ameliorated by the increased expression of MnSOD (1185). ALS linked mutations in *Sod1* can either inactivate or leave active the enzymatic activity but all result in increased misfolding of the protein. The mitochondrial uptake of the three common familial ALS Cu/ZnSOD mutants (G37R, G41D, and G93A) is blocked by the heat shock proteins Hsp70, Hsp27, and Hsp25 (1186). Analysis of the spinal cord mitochondria from transgenic rats harboring the *Sod1*<sup>G93A</sup> mutation revealed the association of the misfolded protein to the cytoplasmic face of the mitochondria in association with an increase in the levels of 33 mitochondrial proteins and a decrease in 21 proteins, the proteins of complex I being particularly affected, in association with a 30% reduction in mitochondrial protein import (1187). In addition, binding of misfolded SOD1 was preferentially associated with VDAC1 resulting in reduced conductance for these outer mitochondrial membrane channels and association with reduced ADP transport across the outer membrane (1179). Mutant SOD1 is also associated with altered mitochondrial morphology in motor neurons. This involved the decline of the cylindrical network morphology of the mitochondria and their substitution by more spherical forms (1188). Hence, studies of the familial ALS SOD1 mutants strongly implicated mitochondrial dysfunction in the etiology of ALS.

While ALS has traditionally been viewed as a specific motor neuron neurodegenerative disease, identification

of additional ALS-associated genes has revealed that gene mutations that cause a variety of other tissue defects can also cause ALS. This implies that systemic cellular defects can result in motor neuron-specific disease. Mutations in the VCP gene had previously been shown to cause inclusion body myopathy (IBM) with Paget's disease of the bone (PDB) and frontotemporal dementia (FTD) or IBMPFD and more recently PD (1189). The IBMPFD knock-in mouse shows progressive vacuolization of mutant muscle myofibrils, centrally located nuclei, cytoplasmic accumulation of TDP-43, ubiquitin-positive inclusion bodies in quadriceps myofibrils and brain, increased number of autophagosomes suggesting impaired autophagy, and increased apoptosis as indicated by elevated caspase-3 activity and increased TUNEL-positive nuclei (1190). Since mutations in the VCP gene have now been found in 1–2% of familial ALS patients (1180,1181), this directly links mitochondrial dysfunction to ALS.

An expanded hexanucleotide repeat (GGGGCC) in the noncoding region of the functionally unknown open reading frame (C9ORF72) at chromosome 9p21 has also been linked to ALS and found to account for 46% of familial ALS and 21% of sporadic ALS in the Finnish population and 24% of familial cases in other populations. The normal allele has between 2 and 23 repeats while the mutant alleles may be in the range of 700–1600 repeats. While antibodies are still poorly characterized, one study suggests that the C9ORF72 protein has a predominantly cytoplasmic and synaptic localization. In addition to accounting for a significant proportion of familial ALS cases, expansion of the C9ORF72 hexanucleotide repeat has also been found in 12% FTD (1178,1182,1191). Hence, the C9ORF72 hexanucleotide repeat mutation, like the VCP mutations, must have a multi-tissue function, impairment of which can cause motor neuron dysfunction.

### 11.4.5 Autism Spectrum Disorders

Autism and autism spectrum disorders (ASDs) are defined as neurobehavioral syndromes associated with deficits in social interaction, impaired communication skills, and repetitive stereotypic behaviors (1192–1194). Neuropathological studies demonstrate that ASD patients have alterations in the synaptic and dendritic organization of the brain (1195).

The prevalence of autism and ASD is currently estimated at 6.7 per 1000 with a male to female ratio of 4:1. Chromosomal mapping studies have identified autism susceptibility loci at 1p, 2q, 5q, 7q, 15q, 16q, 17q, 19p, and Xq, but no one locus has been found to make a predominate contribution. While monozygotic twins are 70% concordant for autism and 90% concordant for ASD, dizygotic twins are only 5% concordant for autism and 10% concordant for ASD (1192,1196–1200). If autism were due to simple Mendelian variation,

we might expect 40–45% of dizygotic twins to be concordant for ASD. That this is not the case suggests that autism involves the interaction of a number of interrelated genetic factors.

ASDs can either be idiopathic or syndromic. Syndromes associated with a predilection to autism include RS, tuberous sclerosis, neurofibromatosis, Angelman syndrome (AS), fragile X syndrome, and Timothy syndrome.

**11.4.5.1 Autism and Chromosomal Genetics.** Chromosomal linkage and candidate gene studies have identified a number of gene loci associated with autism which are important in the structure of the dendrite and synapse. These include the neuroligins (NLGL1-5), neurexins (NRXN1-3), contactins, and contactin-associated proteins (CNTNAP2), and the SHANK3 protein (1196,1201–1205).

Neuroligin interacts with the scaffolding protein, PSD-95, which is associated with glutamate receptor expression. Accordingly, some autistic cases have been linked to glutamate 6 receptor (GRIK2) mutations (1206), and GRIK2 is deleted in a mental retardation family (1207). Autism cases have also been linked to single nucleotide polymorphisms (SNPs) surrounding the glutamate receptor ionotropic NMDA 2A gene (GRIN2A) and the 4-aminoglutarate transferase (ABAT) gene of GABA metabolism (1208).

Homozygosity mapping in inbred families has revealed a number of autism susceptibility loci. Homozygous deletions were observed in the velocardiofacial syndrome region, and 6.4% (5/78) of probands from consanguineous families have been found to harbor homozygous deletions ranging from 18 kb to >880 kb (1209–1211). The association of autism with regional chromosomal copy number variants (CNVs) has been greatly extended using comparative genomic hybridization (CGH). Using an oligonucleotide array with probes separated by 35 kb, Wigler and collaborators examined 118 sporadic cases, 77 multiplex families, and 196 controls. Among the sporadic autism patients, 10% (12/118) were found to have CNVs; in the multiplex families, 3% (2/77) had CNVs; and among the controls only 1% (2/196) had CNVs (1199). These investigators hypothesized that there are two genetic origins for autism CNVs. The majority of CNV cases are de novo mutations affecting only one patient. However, the minority are inherited. Wigler then hypothesized that women may be less prone to be affected, thus accounting for the male bias, though no rationale was given for his assumption (1199,1200). What is clear is that autism can result from a plethora of different gene mutations and thus is oligogenic. Some autism mutations affect structural elements of synapses, excitatory neuronal receptors, and ion channels. However, mutations in Mendelian structural genes for synapse formation cannot explain the plethora of autism susceptibility loci, the discrepancy in concordance between monozygotic and dizygotic twins, or the strong male bias among patients.

#### 11.4.5.2 Autism and Mitochondrial Dysfunction.

Alterations in mitochondrial structure and function have been repeatedly observed in autistic patients (1192,1212,1213). One nDNA-encoded mitochondrial transport enzyme that has been associated with autism is the mitochondrial inner membrane Ca-regulated aspartate/glutamate carrier (AGC). The human genome harbors two AGCs; AGC1 or aralar1 encoded by the SLC25A12 gene on chromosome 2q24, and AGC2 or citrin encoded by the SLC25A13 gene on 7q21.3. AGC1 is expressed in brain, heart, and skeletal muscle and is the only isoform expressed in neurons. AGC2 is the predominant isoform in liver and kidney and is expressed in glia along with AGC1. Both AGCs have four EF-hand  $\text{Ca}^{++}$  binding motifs and are activated by cytosolic  $\text{Ca}^{++}$ .

Initially, ASG1 was linked to autism through two SLC25A12 SNPs (1198) with the higher activity alleles associated with autism (1197). More recently, a three-fold increased AGC1 activity has been reported in the brains of autism patients in association with a 2.7-fold elevation in brain  $\text{Ca}^{++}$  levels (1214).

Alteration in brain AGC1 activity should affect the transport of aspartate into the cytosol. Aspartate is the substrate for N-acetyl-aspartate (NAA), a precursor for myelin. SLC25A12-deficient mice show impaired myelination (1215). However, the AGCs also function in conjunction with the malate/ $\alpha$ -ketoglutarate carrier (MaKC) to permit the exchange across the mitochondrial inner membrane of mitochondrial and cytosolic reducing equivalents ( $\text{NADH} + \text{H}^+$ ). Upregulation of AGC1 would increase the flux of cytosolic  $\text{NADH} + \text{H}^+$  into the mitochondrion, funneling extra reducing equivalents (electrons) into the mitochondrial ETC. This would transiently increase respiration and ATP production, but ultimately overload the ETC, resulting in increased production of toxic ROS and loss of synaptic integrity (1214). Consistent with this scenario, when expression of AGC1 is enhanced in cultured neurons, neurite outgrowth is initially enhanced, but the neurites subsequently died off (1197).

Since cytosolic  $\text{Ca}^{++}$  levels are buffered by the mitochondrial energy-linked uptake of  $\text{Ca}^{++}$ , a mild defect in mitochondrial energy production could result in a chronically elevated brain  $\text{Ca}^{++}$  level. The elevated cytosolic  $\text{Ca}^{++}$  would activate AGC1, increase ROS production, activate the mtPTP, and destroy dendritic connections. Consistent with there being a chronic mitochondrial energy defect, cytochrome c oxidase (COX, complex IV) activity is elevated in autistic brains, a common compensatory response to OXPHOS defects (33,314,1214). Mitochondria from autistic brains also show elevated oxidative damage (1214).

Energetic dysfunction in autistic brains has been detected by functional MRI (1216) and metabolites associated with both methylation capacity (plasma methionine and S-adenosylmethionine/S-adenosylhomocysteine) and antioxidant pathways (plasma cysteine

and glutathione and reduced/oxidized glutathione) are reduced in autistic patients (1217). Screening of autistic patient blood and urine has revealed that free and total carnitines were reduced in blood of a quarter to a third of subjects; urine pyruvate levels were elevated in 4/5 of cases, plasma alanine was elevated in 4/5 of cases, and ammonemia in 3/4 of cases (1218). In another study, 8% of ASD subjects were found to have evidence of mitochondrial dysfunction, including elevated plasma lactate and urine lactate and organic acids (1219). Similarly, plasma lactate was found elevated in 17% of cases, lactate:pyruvate ratios were elevated in 26%, and muscle mitochondrial OXPHOS defects were found in 23% (7/30) of cases (1220). In a Portuguese study, plasma lactates were elevated in 20% of autistic cases, the lactate to pyruvate ratios were increased in 85% of cases, and muscle mitochondrial defects were found in 55% (6/11) of cases (1221). One child that experienced autistic regression following immunization was reported to have an underlying muscle OXPHOS complex I and complex III defect (1222). Finally, in lymphoblastoid cell lines from autism patients and controls, OXPHOS complex I respiration was found to be reduced 40–50 (1223).

Three to five percent of autistic patients harbor an inverted duplication of the chromosome 15q11-q13 region. These patients have elevated urine lactate and serum lactate, pyruvate, and alanine, and their muscle mitochondrial complex III is reduced in association with mitochondrial hyperproliferation (1212,1224).

One autism locus located to chromosome 7q31 was found to have reductions in two candidate genes, IMMP2L and DOCK4. The IMMP2L or IMP2-LIKE (MIM 612323) gene is a component of the mitochondrial inner membrane peptidase (IMP) complex that generates mature, active, mitochondrial proteins by proteolytically removing the targeting presequence of nDNA-encoded proteins. Mutations in this gene were also found in a Tourette patient (1225).

A subset of autistic patients have also been reported to harbor mtDNA mutations. One family harbored a heteroplasmic tRNA<sup>Lys</sup> nt G8363A mutation (1226). Of 12 children who presented with hypotonia, epilepsy, autism, and developmental delay (HEADD), three quarters were found to have abnormal mitochondria, 7/8 OXPHOS defects, and five elevated levels of large mtDNA deletions (1227). Three pedigrees with autism patients were found to harbor the pathogenic tRNA<sup>Leu(UUR)</sup> nt A3243G mutation and the proband of one pedigree was found to have a 75% depletion in muscle mtDNAs (1228).

Autistic symptoms can occur in RS, tuberous sclerosis complex (TSC), neurofibromatosis-1 (NF1), AS, and fragile X mental retardation (FMR), and Timothy syndrome. RS is caused by mutations in the nDNA methyl CpG binding protein (MeCP2) gene (MeCP2) (1229–1231). These patients have been reported to harbor mitochondrial structure aberrations and reductions in muscle OXPHOS complexes I, III, and IV. Mice lacking MeCP2

have increased complex III and core protein 1 gene (Ugcr1) expression, together with reduced OXPHOS coupling (1232–1234).

TSC is a cell overgrowth disorder caused by mutations in either the hamartin TSC1 gene or the tuberin TSC2 gene. Twenty-five percent to 50% of TSC cases exhibit ASD. TSC1 + 2, act through Rheb to regulate TORC1, and TOR has been implicated in regulation of mitochondrial OXPHOS (1235,1236) (Figure 11-1).

NF1 is another overgrowth syndrome associated with ASD (1237). The mtDNAs of NF1 neurofibromas have been found to contain somatic control region mutations (1238) and NF1 has been shown to regulate *Drosophila* mitochondrial ROS production and longevity through a cAMP mediated mechanism (1155).

AS and Prader–Willie syndrome (PWS) result from alterations in the imprinted loci on chromosome 15q11-13, AS resulting from a maternal deficiency and PWS from paternal deficiency. Current evidence suggests that loss of expression of UBE3A is responsible for the AS phenotypes and of SNRPN for the PWS phenotype (1239). We have found that mice lacking UBE3A harbor small and dense hippocampal mitochondria and have reduced OXPHOS complexes II + III (1240).

The FMR protein (FMRP) has recently been shown to be required for the expression of the mitochondrial and cytosolic Cu/Zn superoxide dismutase (SOD1) (1241). SOD1 and MnSOD (SOD2) function to eliminate mitochondrial superoxide generated on the outside and inside of the mitochondrial inner membrane, respectively (1).

Timothy syndrome presents with Long QT syndrome and autism, and has been linked to mutations in the T-type voltage-gated Ca<sub>v</sub>1.2 channel encoded by the CACNA1C gene, most commonly involving the G406R allele (1242). Ca<sub>v</sub>1.2 shows its highest expression in the hippocampus, amygdale, and putamen. A survey of the CACNA1H gene, a close paralog of the Timothy syndrome channel, in 461 autism DNAs revealed six new mutations. Functional studies of two of these, R212C and R902W, revealed extended Ca<sup>++</sup> influx into the cytosol (1243). Cytosolic Ca<sup>++</sup> levels are regulated by mitochondrial Ca<sup>++</sup> uptake, driven by the mitochondrial inner membrane potential ( $\Delta\psi$ ). Excessive Ca<sup>++</sup> uptake and chronically increased oxidative stress can activate the mtPTP and initiate cellular destruction. Therefore, defects in a variety of systems that alter Ca<sup>++</sup> can lead to neuronal impairment.

**11.4.5.3 Mitochondria and Synaptogenesis.** Mitochondria play a central role in neurite outgrowth, axonal polarity, and synaptic plasticity (1244–1247). In Purkinje cells, the mitochondrial anti-apoptosis protein, Bcl-W, interacts with the glutamate receptor  $\delta$  (Grid2). These regulate Ca<sup>++</sup> flux into the cytosol and mitochondria, mitochondrial fission, function, autophagy, and neuronal structure. Inactivating Bcl-2 and Grid2 in mice inhibits mitochondrial fission, blocking the movement of mitochondria into dendritic spines (1248). Therefore,

mitochondrial dysfunction has been implicated in both non-syndromic and syndromic ASD.

**11.4.5.4 Mitochondrial Physiology and Autism.** Mitochondria generate much of the ROS in cells. Of these,  $H_2O_2$  is the most stable and an important second messenger. It can diffuse out of the mitochondrion and into the nucleus-cytosol where it can act on a broad spectrum of kinases and redox sensitive proteins that regulate cell growth, differentiation, inflammation, and death (Figure 11-4). Mitochondrial biogenesis is also regulated by the availability of reducing equivalents in the form of glucose via insulin, the insulin receptor, PI3K, Akt (PKB), and the FOXO pathway and by the glucagon, cAMP, phosphor-CREB pathway. Both the FOXOs and CREB regulate PGC-1 $\alpha$  which induces the expression of OXPHOS genes (1,2) (Figure 11-4). The FOXOs and PGC-1 $\alpha$  are also regulated by acetylation, controlled by SIRT1 and NAD<sup>+</sup> (Figure 11-4). SIRT3 also regulates OXPHOS enzymes activity through acetylation (1249,1250).

The mitochondrial redox status and ROS production directly activate NF- $\kappa$ B which upregulates the inflammatory cytokine genes thus generating inflammation. Hence, dysregulation of AGC in autistic brains would increase ROS, activate NF- $\kappa$ B, and induce inflammation. Bacterial lipopolysaccharide (LPS) stimulates the liver to release the pro-inflammatory cytokines, TNF $\alpha$  and IL-1 $\beta$ . TNF $\alpha$  stimulates oxidation of mitochondrial thioredoxin 2 (Trx2) but not cytosolic Trx1, resulting in the elevation of cellular ROS within an hour of exposure (1251). The increased ROS induces the transcription of HIF-1 $\alpha$ , activates Akt, and thus mTOR, and mTOR increases the protein synthesis of HIF-1 $\alpha$ . HIF-1 then increases inflammatory gene expression. Autistic children have altered antigenic responses (1252,1253), altered immune cell function, and increased pro-inflammatory cytokine levels (TNF- $\alpha$ , interferon (IFN)- $\gamma$ , interleukin (IL)-1 $\beta$ , IL-6, and IL-12) (1252,1254–1265). Therefore, it follows that if autistic children have partial mitochondrial defects, then infections and other immunological challenges could alter their precarious redox balance, precipitating dendritic and synaptic spine withdrawal, and autistic regression. Environmental challenges could also trigger for Ca<sup>++</sup> signaling through the IP3 receptors (1266) which could stimulate the mitochondrial tricarboxylic acid cycle and OXPHOS and ultimately lead to Ca<sup>++</sup> overload and apoptosis (Figure 11-4).

**11.4.5.5 Mitochondrial Explanations of Autism.** Therefore, some of the complexities of autism might then be understood by hypothesizing that mitochondrial defects are a common contribution to autism. Mild mitochondrial defects would preferentially affect the brain, due to its high energy demand and the importance of neuronal Ca<sup>++</sup> regulation. The large number of mitochondrial genes means that many different gene alterations as well as environmental toxins can perturb mitochondrial homeostasis. Since mild mitochondrial diseases such as LHON show a strong male bias in penetrance

(1267–1271), mild mitochondrial defects causing autism would also be expected to show a strong male bias. The low concordance in fraternal twins and the extreme variability in penetrance of autism genes could be the result of variable interactions between polymorphisms in the hundreds of nDNA- and mtDNA-encoded mitochondrial genes. The variability in clinical courses of autistic patients is characteristic of mitochondrial disease, and reflects the many different types of mitochondrial genes and variable severity of their defects. The loss of milestones associated with regressive autism in response to febrile events is also seen in LS and is consistent with the mitochondrial regulation of Ca<sup>++</sup>, ROS, and redox state and their effects on gene regulation and inflammation. Finally, the mild mitochondrial defects such as those proposed to be associated with autism are often too subtle to be detected by current mitochondrial diagnostic tools, explaining why mitochondrial defects have not been consistently found in ASD patients using current mitochondrial diagnostic tools.

## 11.4.6 Psychiatric Disorders

There is growing evidence that psychiatric disorders may have an mtDNA component. An extensive genetic epidemiologic analysis of bipolar affective disorder (BPAD) pedigrees revealed that there was a higher than expected frequency of affected mothers of probands, a 2.3- to 2.8-fold increased risk of illness for maternal relatives, and a 1.3- to 2.5-fold increased risk of illness for offspring of affected mothers. Moreover, 10 pedigrees were observed in which disease transmission was almost exclusively matrilineal, though sequencing of the mtDNA from these pedigrees did not reveal a common mtDNA mutation to which BPAD could be ascribed (427,1272). Patients with PEO associated with multiple deletion syndrome have been reported to have affective disorders including depression, apathy, fatigue, and insomnia (1273), and severe psychiatric disturbance principally involving depression and irritability was observed in several members of the large LHON plus neurologic disease pedigree (577) subsequently found to harbor the MTND6\*LHON14484C and MTND1\*LHON4160C mutations (543). Analysis of the acidification of brains at autopsy has revealed a significant association between increased brain pH and haplogroups (U and Uk). There are suggestions of haplogroup bias in affected patients, and the rate of nucleotide substitutions in the mtDNA was found to be 22% higher in dorsolateral prefrontal cortex of patients with schizophrenia than controls (1274).

## 11.5 MITOCHONDRIAL DEFECTS IN CANCER

Interest in the role of mitochondrial functional alterations in cancer dates back almost 70 years to when Otto Warburg observed that many cancer cells produce excessive lactate while still respiring, a state he called

“aerobic-glycolysis” (1275). Contrary to previous expectations, it is now clear that the mitochondria of cancer cells are not defective (1276). Multiple studies have demonstrated that cells that have been cured of their resident mtDNA ( $\rho^0$  cells) (296,297,1277) have markedly reduced tumorigenicity relative to their mtDNA containing parental counterparts (1278–1281).

Rather than eliminate mitochondrial function, the cancer cell must alter its bioenergetics to shift its metabolic state from that of quiescent and oxidative cells in which most calories are oxidized to generate energy to that of an actively replicating cell in which much of the calories must be directed to cellular biogenesis frequently in low oxygen environments (1282). Thus, most cancer cells acquire mutations that alter the PI3K-PTEN-Akt pathway to increase glycolysis and biogenesis at the expense of oxidative metabolism (1283), the HIF-1 $\alpha$  system to optimize growth at low oxygen levels (1284), and the myc gene to increase glutamine metabolism to generate metabolic intermediates for growth and redox control (1282).

While the mitochondria of cancer cells are not defective, they are altered and this commonly involves mutations in the mtDNA. This is clear since aging is the most significant risk factor for most solid tumors and caloric restriction in rodents markedly reduces cancer risk (1276,1285–1289), and it is the accumulation of somatic mtDNA mutations that has been repeatedly associated with aging (1,452).

The importance of mutations in mitochondrial genes for cancer was clearly established by the discovery that mutations in certain nDNA-encoded mitochondrial genes results in specific types of tumors (296,297,1277–1281). Mutations in SDH have been associated with hereditary paragangliomas and pheochromocytomas. SDH is composed of four subunits. SDHA binds the substrates succinate and fumarate and contains an FAD cofactor. SDHB contains the iron sulfur center electron carriers. SDHC and D constitute the inner membrane cytochrome b and coenzyme Q binding sites, SDHD being the smaller cytochrome b subunit (cybS) while SDHC is the larger cytochrome b subunit (cybL). In addition, SDH assembly involves two factors, SDH assembly factors 1 (SDHAF1) and 2 (SDHAF2). All familial paragangliomas are associated with germline heterozygous mutations in SDH subunits or SDHAF2 which are homozygous mutant in the tumors (1290). Mutations in SDHD (1291), SDHC (1292), and SDHB (1293,1294) have repeatedly been observed, but only one cancer patient has been reported with a mutation in SDHA and this resulted in an abdominal catecholamine-secreting paragangliomas (1290). SDHAF2 (SDH5) encodes a conserved protein necessary for incorporation of the FAD cofactor into SDHA. SDHAF2 mutations are associated with benign multifocal head and neck paragangliomas (1290).

The pathophysiology of SDH mutation cancer formation has been proposed to be the result of excessive succinate secretion by mitochondria via the dicarboxylate carrier. The succinate is thought to inhibit the

$\alpha$ -ketoglutarate-dependent prolyl hydroxylases (PHDs 1-3) which, together with the von Hippel-Landau (VHL) gene product, degrade the HIF-1 $\alpha$  transcription factor (1295). The HIF transcription factors play a central role in the shift from oxidative to glycolytic metabolism of cancer cells (1284,1290,1296–1299).

Mutations in the TCA cycle enzyme fumarate hydratase (FH) are associated with leiomyomatosis (multiple cutaneous uterine leiomyomata) and renal cell cancer (1300,1301). Cultured cells harboring FH mutations can produce up to a 100-fold increase in fumarate, 7-fold increase in succinate, and marked decrease in malate and citrate (1302). As with SDH deficiency, the dominant pathophysiological hypothesis for tumor formation is that fumarate inhibits the PHD enzymes thus stabilizing and activating the HIF-1 pathway (1303). An alternative hypothesis is that the excessive fumarate results in the succination of KEAP1 and the activation of the Nrf2 stress response pathways. Among other genes, activation of Nrf2 results in the induction of heme oxygenase 1 (HMOX1). HMOX1 degrades heme and since heme is synthesized by the condensation of glycine with succinyl-CoA to yield  $\delta$ -aminolevulinic acid (ALA) via mitochondrial ALA synthase, this would remove the excessive succinyl-CoA that would accumulate from the FH blockade (1302). Since many tumors become dependent on glutaminolysis for generation of the TCA cycle intermediates through the activation of myc (1304,1305), the induction of HMOX1 helps maintain the carbon flux through the mitochondrion thus promoting cellular biogenesis.

While tumors associated with SDH and FH mutations are homozygous mutants, the mutations in isocitrate dehydrogenase isoforms 1 and 2 (IDH1 and IDH2) found in gliomas, secondary glioblastomas, and acute myeloid leukemia (AML) are heterozygous mutations. The IDHs reversibly convert isocitrate to  $\alpha$ -ketoglutarate coupled with the reduction of NADP<sup>+</sup> to NADPH. IDH1 is located in the cytosol while IDH2 is found in the mitochondrion. In gliomas, the IDH1 neoplastic mutations are R132C and R132G while IDH2 mutations involve R132 and R172. In AML, the mutations are found in IDH1 at R132 and IDH2 at R172K and R140Q. All of these mutations change the activity of IDH to one which uses NADPH to reduce  $\alpha$ -ketoglutarate to R(-)-2-hydroxyglutarate (2HG). It has again been proposed that 2HG inactivates PHDs and activates HIF-1 $\alpha$ . As a result, 2HG has been called an “oncometabolite” (1306,1307).

While SDH, FH, and IDH1 and 2 perturb mitochondrial metabolic pathways, reductions in the activity of the mitochondrial RNA helicase protein SUV3 as a result of mutations in the Suv3 gene result in the destabilization of the mtDNA. Partial reduction in SUV3, which is seen in 60% of breast cancers (1308), is associated with the accumulation of shortened mitochondrial RNA species, a shift in mitochondrial morphology from tubular to granular, impaired mitochondrial protein synthesis, decreased mtDNA copy number, down-regulation of OXPHOS enzymes, increased ROS generation, reduced

membrane potential, and reduced ATP production (1309). Mice heterozygous for a Suv3 null mutation also exhibit reduced OXPHOS enzyme activity and mtDNA copy number, increased somatic mtDNA mutation rates, and markedly elevated tumor rates. When Suv3+/- female mice are mated with wild-type males over successive generations, the life span of the mice progressively decreases until the F4 generation when the mice become infertile. This reduction in life span and increase in tumor rate is retained in descendants of Suv3+/- females that have an Suv3+/+ genotype. Hence, the partial reduction in SUV3 destabilizes the mtDNA, but it is the presence of the mutations in the mtDNA that cause the decreased life span and predisposition to cancer (1308).

The discovery that Suv3+/- induced mtDNA damage is oncogenic now makes the observations of mtDNA mutations in cancer cells relevant. The first clear evidence that mtDNA mutations might play an important role in neoplastic transformation came with the report of a renal adenocarcinoma that was heteroplasmic for a 294-np in-frame deletion in the mtDNA ND1 gene. This deletion generated a truncated mRNA, confirming that the mutant mtDNA resulted in mitochondrial functional defect (1310). Subsequently, a variety of mtDNA coding region and control region mutations have been reported cancer cells including colon cancer cells (1311–1313), head and neck tumors (1314), astrocytic tumors (1315), thyroid tumors (1316,1317), breast tumors (1318), and prostate tumors (1319–1322). Comparison of the reported cancer cell mtDNA mutations with those that have been identified as markers for the various mtDNA haplogroups has revealed that more than half of the cancer mutations are the same variants that have been found to be haplogroup specific variants. Since many of these variants have been proposed to be adaptive (360,361), it is possible that cancer mtDNA mutations may confer at least two advantages to cancer cells, contributing to the neoplastic transformation process and permitting cancer cells to adapt to their varying environmental challenges (1323).

Because of the large number of critical bioenergetic and metabolic functions of the mitochondrion, mutations in mitochondrial genes might contribute to neoplastic transformation in a number of different manners. By analogy to the SDH, FH, and IDH mutations, mtDNA mutations might alter mitochondrial metabolism to redirect metabolites from terminal oxidation into biosynthetic pathways permitting stimulation of cell growth. Alternatively, alteration of mitochondrial OXPHOS might alter mitochondrial ROS production and thus alter signal transduction pathways. Partial increases in ROS have long been known to act as a potent cellular mitogen. Only when exposed to excessive levels of ROS will cells undergo apoptosis (12,1324–1326). Low levels of ROS are thought to be mitogenic through their interaction with various kinases (Src kinase, protein kinase C, mitogen-activated protein kinase, and receptor tyrosine kinases), as well as with different transcription factors

(Fos, Jun, NF- $\kappa$ B) (389). Furthermore, the bifunctional protein apurinic/apyrimidinic endonuclease/redox factor-1 (APE/Ref1Red/Ox) plays a role in the DNA base excision pathway but also in the redox regulation of the transcription factors Fos, Jun, NF- $\kappa$ B, PAX, HIF-1 $\alpha$ , and p53 (390,391,1327,1328). The role of mitochondrial ROS in cancer is supported by the observations that mice heterozygous for the MnSOD knockout locus have a 100% increase in cancer incidence (1329), many types of tumors have reduced MnSOD, transformation of certain tumors with the MnSOD cDNA can reverse the malignant phenotype, and a cluster of three mutations in the MnSOD gene promoter region that alter AP-2 binding and promoter efficiency are found in a number of tumors (389,1330).

Further evidence of the importance of mtDNA mutations and mitochondrial ROS production in neoplastic transformation comes from studies of complex IV (COX) mutations in prostate cancer. A proteomic survey of prostate cancer epithelium cells isolated by laser capture microscopy revealed that the ratio of nDNA-encoded subunits (COX IV, Vb, and VIc) to mtDNA-encoded subunits (COI and II) was increased in most prostate tumors (1331). This alteration in the ratio of nDNA to mtDNA COX subunits in prostate cancer can result from mutations in the mtDNA COI gene. Both germline and somatic COI gene mutations have been identified in prostate cancer (1322). An analysis of prostate cancer specimens revealed that 11% harbored germline COI missense mutations, 4 of which were found in multiple independent patient tumors, often on different background mtDNA haplotypes (T6253C, C6340T, G6261A, and A6663G) and these changed highly conserved amino acids (conservation index CI=69–97%) (1322). A COI missense mutation that caused a partial complex I defect would be expected to increase cellular ROS production (314,319). Three other prostate cancer COI mutations were heteroplasmic and thus either recent germline mutations or somatic mutations. These included G5949A-G16X (Stop), T6124C-M74T (CI = 95%), and C6924T-A341S (CI = 100%) (1322). The G16X mutation was particularly informative since it was found to be homoplasmic mutant in the tumorigenic epithelial cells, but homoplasmic wild type in the adjacent normal epithelial cells, which was confirmed by immunohistochemical staining for the COI protein. Therefore, this G16X mutation must have arisen de novo at the time of neoplastic transformation and been strongly selected for in the cancerous cells (1322).

The physiologic significance of mtDNA mutations in cancer cells was demonstrated by introducing a known pathogenic mtDNA mutation into the prostate cancer cell line PC3 via transmitochondrial cybrid fusions (294). PC3 prostate cancer cells were cured of their resident mtDNAs by treatment with the mitochondrial poison rhodamine 6G and then fused with cytoplasts from either homoplasmic mutant (T8993G) or homoplasmic

wild-type (T8993T) cell lines (1322) derived from a patient who was heteroplasmic for the pathogenic ATP6 np T8993G (L156R) mutation (591). This mutation reduces mitochondrial ADP production (591) but also increases ROS production (604). When injected into immune compromised mice, the PC3 cells harboring the normal T8993T base barely grew while the PC3 cybrids with the mutant T8993G base generated rapidly growing tumors that killed the mice (1322). Staining the cellular nodules from the T8993T and T8993G cybrid tumors with dihydroethidium revealed that the mutant T8993G tumors were making much more ROS than the wild-type T8993T nodules (1322). Since MnSOD has been found to be reduced in precancerous intraepithelial neoplastic lesions and in prostate cancer by immunohistochemical and in situ hybridization studies (1332,1333) and prostate cancer cells have a 42% increase in cytoplasmic staining for APE/Ref1<sup>Red/Ox</sup> (1334), these data support the hypothesis that mitochondrial ROS production contributes to the etiology of prostate cancer.

The relevance of increased mitochondrial ROS production to the etiology of other forms of cancer is demonstrated by a tumorigenic mouse cell line found harboring an mtDNA ND6 missense mutation at nt G13997A and frameshift mutation at 13885insC. These cells exhibited a substantially increased ROS production and growth rate, traits that could be transferred from one cell to another by cybrid fusions and resulted in the conversion of low tumorigenic cells to high tumorigenicity (1335). A human cell line harboring a homoplasmic mtDNA ND5 frameshift mutant grew less rapidly and had a lower neoplastic potential than cells that were heteroplasmic for the frameshift mtDNA and a normal mtDNA, the increased growth rate and tumorigenicity of the heteroplasmic cells correlating with increased mitochondrial ROS (1336). Direct proof of the importance of mitochondrial ROS in tumorigenesis has been demonstrated in mice expressing the polyoma middle T oncoprotein which predisposes to lung and breast tumors. Introducing the mitochondrially targeted catalase (mCAT) transgene which removes matrix H<sub>2</sub>O<sub>2</sub> reduced tumor formation (1337). Similarly, mice heterozygous for the adenomatous polyposis coli multiple intestinal neoplasia gene (APC<sup>Min/+</sup>) combined with the heterozygous Tfam allele (Tfam<sup>+/-</sup>) had an increased frequency of intestinal tumors in association with reduced levels of TFAM and mtDNA and increased antimycin A-accentuated ROS production. The frequency of tumors in these mice declined when combined with the mCAT transgene (1338).

In addition to the initiation of tumorigenesis, mitochondrial dysfunction has been shown to contribute to tumor invasiveness through mitochondrial stress activation of mitochondrial retrograde signaling. Ethidium bromide induced 50–80% reduction of mtDNA copy number in the noninvasive, established, mouse myoblast cell line, C2C12, which resulted in cells showing the features of the epithelial–mesenchymal transition together

with a vastly increased invasiveness in a xenotransplantation assay (1339). The reduced mtDNA copy number resulted in reduction in the mitochondrial membrane potential and increased cytosolic Ca<sup>++</sup>. The Ca<sup>++</sup> acts through the Ca<sup>++</sup> responsive phosphatase calcineurin to activate NF-κB via an IκBβ-dependent pathway. This activates an enhanceosome and upregulates the expression of cathepsin L, the ryanodine receptor 1, Glut4 and IGF-1R, and so on leading to altered cell morphology, metabolic shift, resistance to apoptosis, and increased invasive behavior (1340,–1343).

## 11.6 THERAPEUTIC APPROACHES TO MITOCHONDRIAL DISEASE

As the importance of bioenergetic dysfunction to a broad spectrum of human disease becomes apparent, the need for effective therapeutics for mitochondrial dysfunction is becoming acute. Deficiencies in mitochondrial function might be treated by either metabolic or genetic therapies.

### 11.6.1 Metabolic Therapeutics

Metabolic therapeutic strategies could focus on three potential mitochondrial drug targets: energy generation, ROS production, and apoptosis modulation through the mtPTP.

**11.6.1.1 Modulating Mitochondrial Energy Production.** A variety of metabolic strategies have been used to increase mitochondrial energy production. Various combinations of vitamins have also been used to treat mitochondrial disease patients with varying levels of success (683) though metabolic supplementation to bypass metabolic blocks has been successful in selected cases. One CPEO patient with respiratory failure due to a predominantly complex I defect was successfully treated with succinate plus CoQ. The succinate introduced reducing equivalents into the ETC via complex II, thus bypassing the complex I block, and the CoQ<sub>10</sub> would enhance the transfer of the electrons from complex II to complex III. This treatment permitted the patient to be respirator independent as long as the therapy continued (775). In a patient with complex III deficiency due to a CYTB chain termination mutation (623), the complex III block was bypassed by giving ascorbate and menadione. This treatment significantly improved her muscle strength and mitochondrial energy production, as assessed by <sup>31</sup>P-MRS (622,1344).

Since dihydroorotate CoQ oxidoreductase (dihydroorotate dehydrogenase) uses the ETC for an electron sink for reduced CoQ<sub>10</sub>, the ETC is required for de novo pyrimidine biosynthesis. Consequently, it has been proposed that providing uridine might be beneficial to mitochondrial disease patients. Preliminary studies have suggested that supplementation with triacetyluridine, bioavailable form of uridine, may be beneficial for some patients (1345).

L-arginine has been proposed as a treatment for the stroke-like episodes associated with the MELAS syndrome.

Current trials are focusing on patients harboring the tRNA<sup>Leu(UUR)</sup> 3243A>G mutation. These stroke-like episodes in MELAS show ischemia across vascular beds which has led to the hypothesis that they are the results of more global vasoconstriction, perhaps due to the inactivation of the vascular endothelial cell vasodilator NO by mitochondrially generated ROS. By providing L-arginine either orally or intravenously, it is envisioned that the NOS will use the L-arginine substrate to generate NO and relieve the vasoconstriction. Preliminary reports look promising (1346–1348), though additional clinical trials are required to determine the reliability and generality of the therapy.

Dichloroacetate (DCA) has been used to stimulate PDH and reduce lactate production. DCA inhibits pyruvate dehydrogenase kinase (PDK) and PDK inactivates PDH through phosphorylation of the E1 $\alpha$  subunit. Therefore, DCA treatment activates PDH driving pyruvate into the mitochondrion to generate acetylCoA and NADH. While DCA can reduce lactate in patients with severe neonatal lactic acidosis due to partial PDH deficiency, when patients harboring the 3243A>G mutation were treated with DCA, limited success was observed in ameliorating clinical symptoms (1349–1351) and in one DCA trial of 3243A>G patients the trial was suspended due to a high incidence of drug-induced peripheral neuropathy (1350).

Mitochondrial energy output could be increased by upregulation of the mitochondrial mass. Caloric restriction has been shown to increase mitochondrial biogenesis and longevity in a variety of animal models, acting in part through the sirtuins (1352,1353). Therefore, mitochondrial energy output might be enhanced in patients through activation of Sirt1 by using resveratrol or its analogs (SRT1720, SRT2183, etc.). The success of this approach has already been reported for several age-related diseases including type 2 diabetes (1354). Activation of SIRT1 can stimulate mitochondrial biogenesis and aerobic capacity in mice through deacetylation and activation of PGC-1 $\alpha$  (1353) and thus could provide therapeutic benefits for mtDNA disorders (1355).

Overexpression of PGC-1 $\alpha$  was found to delayed onset of symptoms in a COX10 knockout mouse model of COX deficiency muscle disease. Similar benefit was obtained by activating the PPAR/PGC1 $\alpha$  pathway using the PPAR agonist bezafibrate (1356). Bezafibrate has been shown to increase several mitochondrial functions in mitochondrial patient cell lines (1357,1358) and to partially ameliorate symptoms in a mouse model of HD (1359). The PPAR $\gamma$  agonists such as rosiglitazone and pioglitazone have been found to increase mitochondrial biogenesis in mouse brain (1360) and reported to show cognitive and functional improvement in ApoE  $\epsilon$ 4 noncarriers (1361). However, conflicting reports on the efficacy of rosiglitazone and pioglitazone in treating AD mean that this approach to therapy requires additional exploration (1362).

The PPARs are members of the nuclear receptor gene family which also interacts with the energy monitoring

adenosine monophosphate activate protein kinase (AMPK) to form a regulatory network (1363). PPAR $\delta$  agonist GW1516, in association with exercise, increases oxidative muscle fibers in mice. AMPK, acting through PPAR $\delta$ , can also increase endurance exercise capacity. Treatment of sedentary mice for 4 weeks with the AMPK agonist AICAR induced 32 genes linked to oxidative metabolism, 30 of which are induced in PPAR $\delta$  transgenic mice. The AICAR treated mice ran 23% longer and 44% farther than untreated mice (1364). Therefore, activation of the AMPK-PPAR $\delta$  pathway has the potential to increase mitochondrial muscle function and thus treating MM.

**11.6.1.2 Modulating Mitochondrial ROS and REDOX.** While antioxidants such as vitamin E, ascorbate, and lipoic acid are commonly administered to mitochondrial disease patients, their efficacy remains variable (683,1365). CoQ<sub>10</sub> has been given to mitochondrial disease patients based on the logic that the CoQ<sub>10</sub> would enhance electron transfer into the ETC and also act as antioxidants. While routinely provided the success of CoQ<sub>10</sub> in treating mitochondrial disease patients has been variable (1214,1366). CoQ<sub>10</sub> supplementation is beneficial for that subset of mitochondrial disease patients that have mutations in one of the steps in CoQ<sub>10</sub> biosynthesis. Patients with primary CoQ<sub>10</sub> defects are relatively rare and can present with a spectrum of clinical manifestations including encephalomyopathy, LS, severe multisystem infantile disease, cerebellar ataxia, or pure myopathy (858,859,1367,1368).

The antioxidant therapeutic potential of vitamin E and CoQ have been increased by linking them to the positively charged alkyltriphenylphosphonium ion (TPP<sup>+</sup>), thus targeting the compounds to the mitochondrial matrix (1369–1371). The combination of CoQ<sub>10</sub> with TPP<sup>+</sup> resulted in the compound MitoQ (mitoquinone mesylate: [10-(4,5-dimethoxy-2-methyl-3,6-dioxo-1,4-cyclohexadienyl) decyl triphenylphosphonium methanesulfonate]) (1372–1375). MitoQ has been found to collect electrons from complex II and glycerol-3-phosphate dehydrogenase, but is a poor substrate for complex I, complex III, and the electron-transferring flavoprotein (ETF): quinone oxidoreductase. Therefore, it is thought that MitoQ acts primarily as an antioxidant and does not participate in the ETC (1376,1377). MitoQ has been used to treat a number of animal disease models. Among these, MitoQ was recently used to treat the 3xTg-AD model of AD. A 5-month MitoQ regime resulted in prevention of cognitive decline, oxidative stress, A $\beta$  accumulation, astrogliosis, caspase activation, and synaptic loss (1378). This indicates that AD is associated with mitochondrial oxidative stress and that mitochondrially targeted antioxidants may be beneficial for a variety of complex diseases.

Other derivatives of CoQ<sub>10</sub> have altered the structures of the hydrophobic side chain to permit greater bioavailability or altered the quinone and side chain to alter the redox potential of the quinone. One CoQ<sub>10</sub> analog, idebenone

(2,3-dimethoxy-5-methyl-6-(10-hydroxydecyl)-1,4-benzoquinone), has received particular attention, since its shorter side chain permits the quinone to more readily cross the blood–brain barrier (1366). The most extensive studies on idebenone have been applied to Friedreich's ataxia, an autosomal recessive disease which manifests as diabetes mellitus and hypertrophic cardiomyopathy due to a defect in frataxin, a mitochondrial protein important in iron homeostasis loss of which results in increased mitochondrial oxidative stress (22). Treatment of Friedreich's patients with idebenone have been reported to ameliorate the cardiomyopathy (1379,1380) and high doses have been reported to provide some neurological protection (1381). However, early treatment of patients is likely to be most beneficial to minimize accumulated mitochondrial and tissue damage.

Idebenone has been reported to be beneficial in treating LHON in both open label (1382,1383) and a double-blind trial (1384) studies. Idebenone has also been reported to increase complex I activity in fibroblasts from patients harboring the ND4 11778 and ND1 3460 LHON mutations (1385).

Another CoQ analog, EPI-743, has been used to treat both a range of mitochondrial disease patients (1386) and LHON patients (1387). In both open label studies, most patients reported beneficial effects and in the general mitochondrial disease patient study, the redox status of the patients' brains detected by technetium-99m-hexamethylpropyleneamine oxime (HMPAO) single photo emission computer tomography (SPECT) improved in parallel with their well-being (1386).

Even more effective antioxidant therapy might be achieved by using mitochondrially targeted catalytic antioxidants. These include the superoxide dismutase mimetics which catalytically destroy the mitochondrial ROS. One of these, manganese-5,10,15,20-tetrakis-(4-benzoic acid) porphyrin (MnTBAP), has proven particularly effective in treating the dilated cardiomyopathy that develops in mice genetically deficient in MnSOD (Sod2  $-/-$ ) which die at a mean age of 8 days. Death is secondary to the ROS inactivation of the mitochondrial iron–sulfur center enzymes. Unfortunately, MnTBAP does not readily cross the blood–brain barrier, and the MnTBAP-treated animals proceed to develop movement disorders in association with a spongiform encephalopathy of the motor centers (460). Treatment of the MnSOD-deficient animals with the salen manganese complexes EUK-8, -134, and -189, which do cross the blood–brain barrier, protected these animals from both the cardiomyopathy and the spongiform encephalomyopathy (1158). Finally, growing *C. elegans* in these salen manganese complexes extended its life span (1388). Hence, mitochondrially targeted antioxidant enzymes may have promise in treating certain aspects of mitochondrial disease.

**11.6.1.3 Regulation of Mitochondrially Induced Apoptosis via mtPTP Ligands.** A third approach to treating mitochondrial disease would be to inhibit the

mtPTP and thus delay cell loss due to apoptosis. This is still a new area.

Since apoptosis can be initiated by the activation of the mtPTP, the manifestations of mitochondrial disease might be ameliorated by treatment with inhibitors of mtPTP activation (1). Cyclosporin A is a specific inhibitor of cyclophilin D which regulates the mtPTP and could potentially be used in treatment (33). However, cyclosporine A is also immunosuppressant acting through calcineurin. Hence, cyclosporin A is not appropriate for use by mitochondrial disease patients. Recently, analogs of cyclosporin A have been developed which still bind to cyclophilin D but not to calcineurin, thus inhibiting the mtPTP with affecting immune function. An example is Debio 025 (1389). The potential application of this strategy has been demonstrated to be beneficial on patients and mice with mutations in the extracellular matrix protein gene for collagen VI, specifically Bethlem myopathy and Ullrich's congenital muscular dystrophy. Surprisingly, the clinical features of these diseases can be markedly reduced simply by treating with mtPTP inhibitors (1390–1393).

Nortriptyline, a tricyclic depressant, has been shown to inhibit the activation of the mtPTP. In a mouse model of ALS it delayed the onset of symptoms and increased life span (1394). These observations support the hypothesis that modulating the mtPTP may be relevant to a much wider range of clinical problems than simple mitochondrial disorders.

## 11.6.2 Mitochondrial Gene Therapy

Diseases resulting from mtDNA mutations can also be treated by gene therapy. Mitochondrial gene therapy can include both somatic therapy to ameliorate symptoms and germline therapy to eliminate maternally inherited pathogenic mutations.

### 11.6.2.1 Somatic Mitochondrial Gene Therapy.

Somatic mitochondrial gene therapy could take three approaches: direct genetic modification of an nDNA-encoded mutant mitochondrial gene, insertion of a modified mtDNA protein gene into the nucleus and redirection of the normal polypeptide back to the mitochondrion, and direct modification of the mtDNA.

Somatic gene therapy approaches include efforts to modulate the proportion of mutant and wild-type mtDNAs in heteroplasmic cells (heteroplasmy shifting), efforts to directly alter the mtDNA genotype of transcriptional products, and efforts to introduce a corrected gene copy into the nucleus and have the product redirected back to the mitochondrion. Heteroplasmy shifting can be accomplished by either selecting for increased percentages of the normal mtDNA or by using approaches to selectively destroy the mutant mtDNAs. Metabolic selection to enrich for the normal mtDNAs has been accomplished by treatment of cell heteroplasmic for the NARP/MILS ATP6 T8993G mutation in medium containing galactose and oligomycin and observing enrichment for the

wild-type leucine at codon 156 containing mtDNA over the mutant arginine mtDNA (1395). Similarly, growth of cells heteroplasmic for an mtDNA 1.9kb deletion in ketogenic metabolites (acetoacetate,  $\beta$ -hydroxybutyrate, or both) resulted in the enrichment of the wild-type mtDNA from 13% to 20–23% after 5 days (1396).

Heteroplasmic shifting has also been achieved by targeting site-specific restriction enzymes to the mitochondrial which either selectively digest the mtDNA harboring the mutant mtDNA or enrich for the desired mtDNA (1397). In NARP/MILS, the wild-type ATP6 gene sequence 8993T was enriched over the mutant by inserting a mitochondrially targeted transgene for the SmaI restriction endonuclease into the nucleus and having the protein imported into the mitochondrion. There the SmaI selectively cleaved the mutant mtDNAs (1398). Although not all mtDNA mutants create a usable restriction site, a more generalizable approach could be achieved using the sequence specificity of zinc finger DNA-binding protein which when appended to a restriction endonuclease creates highly sequence-specific zinc finger nucleases (ZFNs) (1399). These approaches have been utilized to shift the percentage of two different mtDNAs in cells and animals and have been delivered by AAV (1400–1402).

Efforts to directly alter the replication of mutant mtDNAs have utilized mitochondrially targeted PNAs which have a *N*-(2-aminoethyl)-glycine peptide backbone connected to standard purine and pyrimidine bases which can base pair with nucleic acids. Since the peptide backbone is uncharged, PNAs bind tightly to nucleic acids. In *in vitro* mtDNA replication studies, a PNA synthesized complementary to the common 4977-np deletion breakpoint inhibited the replication of the deletion template 80% without affecting the replication of the normal template. Similarly, a PNA complementary to the MERRF A8344G variant inhibited replication of the mutant mtDNA by about 75% but did not inhibit the normal mtDNA. PNAs have also been observed to be taken up by mammalian cells (1403). This system has been further elaborated by coupling the PNA to the 4-thiobutyltriphenylphosphonium ion through a disulfide bond. This construct was rapidly taken up by the 143B osteosarcoma cells studied. However, the disulfide bond was then reduced in the cytosol, releasing the PNA. Consequently, the PNA remained in the cytosol while the 4-thiobutyltriphenylphosphonium ion continued into the mitochondrion (1404).

Further modification was able to stabilize the PNA–TPP linkage with the construct delivered to the mitochondrion. Unfortunately, the 11 base MERRF 8344G PNA was unable to shift the percentage of the 8344G mutant mtDNAs in cultured cells (1405). To increase the mtDNA binding capacity of the PNA–TPP constructs, the controls have been linked to benzoylbenzoic acid. This benzophenone system, once bound to the mtDNA through the PNA, can then be cross-linked to the mtDNA by UV photoactivation (1406).

An alternative approach would be to target DNA directly to the mitochondrion. A fluorescein-labeled

oligonucleotide has been introduced into the mitochondria of cells by covalently linking the amines at the 3' end of the oligonucleotide to those of the mitochondrial targeting peptide from ornithine transcarbamylase using glutaraldehyde. When this construct was encapsulated into liposomes and the complex exposed to skin fibroblasts, the oligonucleotide-targeting peptide was deposited in the cytosol and subsequently taken up into the mitochondria, with the mitochondrial fluorescence persisting up to 8 days (1407). While this procedure targeted the oligonucleotide to the mitochondria, the covalent linkage of the oligonucleotide to the protein would limit its bioavailability. As an alternative, oligonucleotides have been hybridized to PNAs which are in turn covalently linked to mitochondrial targeting peptides. The mt targeting peptide-PNA:homologous oligonucleotide-labeled complex was then introduced into myoblast and myotube cells using either branched-chain polyethylenimine or streptolysin O permeabilization. Under these circumstances, the “targeting peptide-PNA:oligonucleotide-labeled” constructs were delivered to the cytosol and then rapidly taken up by the mitochondria. Moreover, colloidal gold-labeled oligonucleotides could be observed in the mitochondrial matrix by electron microscopy (1408). While all of these approaches suggest that it may be possible to modify the mtDNA via exposure of cells to exogenous DNA or PNA, no successful alteration of the mtDNA within a living cell has yet been documented.

The third approach that is being actively pursued is to introduce mtDNA gene derivatives into the nDNA, have the gene transcribed, and the resulting protein returned to the mitochondrion. This allotopic mtDNA gene expression has been used for gene products that are derived from very different species or relatively similar mammalian species. Defects in mitochondrial complex I genes have been complemented by introducing the yeast NDI1 (NADH dehydrogenase) gene which can oxidize NADH and transfer the electrons to CoQ via a single polypeptide, though in the absence of proton pumping.

An OXPHOS defect in CHO cells deficient in an nDNA-encoded complex I has been treated by transfection with a plasmid carrying the yeast NDI1 gene, which encodes a single polypeptide. NDI1 transformation of the gene restored the NADH oxidase activity, resulting in complex I that was insensitive to rotenone but sensitive to flavone, characteristics of the yeast but not mammalian NADH dehydrogenase (1409). A high-expression nDNA NDI1 transformant was found to reconstitute the NADH-dependent respiration; the P:O ratio on malate/glutamate substrates to two-thirds that of the wild-type human cells, which would be expected since the yeast NADH dehydrogenase lacks a coupling site; and the ability to grow on galactose (1410). The efficacy of transfer of the yeast NDI1 gene was greatly increased by its introduction into an AAV vector (1411). This AAV-NDI1 transduction system was then used to transduce the yeast NDI1 gene into mouse and rat neuronal cells (1412). Moreover, this AAV-NDI1 vector was used to

transduce the brain substantia nigra and striatum as well as the skeletal muscle of rats (1413).

As a complement to the yeast Nid1 NADH dehydrogenase gene complementation, the ascidian *Ciona intestinalis* cyanide-insensitive and SHAM sensitive alternative oxidase (AOX) has been used to oxidize the reducing equivalents of reduced CoQ to water. This can complement complex III and complex IV deficiency when incorporated into mammalian and *Drosophila* cells (1414–1419). Furthermore, in a *Drosophila* of neurodegenerative disease in which mitochondrial dysfunction was generated by downregulating a subunit of mtDNA polymerase in cholinergic, serotonergic, and dopaminergic neurons, mitochondrial function can be restored by expression of AOX (1418).

Moreover, a combination of the Ndi1 NADH dehydrogenase gene as well as the AOX CoQ/oxidase gene is able to restore respiratory function and uridine independence in mouse cells lacking mtDNA ( $\rho^0$  cells) (1419). Therefore, complementation of mitochondrial respiratory defects by introduction of heterologous genes is potentially promising for the treatment of severe mitochondrial disease.

Defects in nDNA-encoded mitochondrial genes can potentially be treated by reintroduction of a normal copy of the gene into the nucleus. The feasibility of this approach has been demonstrated in the treatment of the muscle mitochondrial energy deficiency associated with null mutations in the heart-muscle isoform of the ANT1. AAV carrying the Ant1 cDNA have been used to transduce mouse Ant1-deficient fibroblasts, myoblasts, and skeletal muscle derived from an Ant1 knockout mouse 227. Like human ANT1 mutant patients, the Ant1 knockout mouse was found to harbor multiple cardiac mtDNA deletions (903). AAV–Ant1 cDNA transduction partially restored the mitochondrial ANT1 activity and mitochondrial export of ATP, and significantly reduced the muscle histopathology associated with the Ant1 defect (950).

Nuclear DNA transformation and transduction is also being explored as a system for treating mtDNA polypeptide gene mutations such as NARP/MILS ATP6 T8993G L156R mutation (591) and LHON ND4 G11778A R340H (4). The logic involves the cloning of the mtDNA gene that harbors the pathological mutations, correcting the genetic code of the mtDNA gene to be compatible with cytosolic translation, adding an N-terminal mitochondrial targeting sequence (MTS) to return the protein to the mitochondrion, adding the necessary nuclear transcription and translation signals, and delivering the construct to the nucleus so that it can be transcribed, translated on cytosolic ribosomes, and targeted back to the mitochondrion. This process is known as allotopic expression. The first application of this strategy was an attempt to correct the complex V defect associated with the ATP6 gene T8993G mutation which reduces mitochondrial ATP production about 70% (301). Transformation of ATP6 T8993G cells with a FLAG-tagged ATP6 gene modified

for the universal code and fused to the COX8 targeting peptide resulted in the import of the nDNA ATP6 polypeptide into the mitochondrion, assembly into complex V, increased mitochondrial ATP production, and improved growth on galactose medium (1420).

This same strategy is being developed for the allotopic treatment of LHON. In LHON, the affected cells are the RGCs which lie at the surface of the retina adjacent to the vitreous. Therefore, viral transduction can be achieved by delivering the viral particles into the vitreous. Two groups are actively pursuing this approach, Dr Guy and Dr Corral-Debrinski (1421,1422). The first objective of the Guy team was to develop a mouse model of LHON. In one experiment, they delivered a ribozyme to the RGC that degraded the mRNA for the complex I NDUFA1 gene resulting in destruction of RGC and optic nerve axons (1423). In the second model, they transduced a hammerhead ribozyme to destroy the mRNA for the mitochondrial MnSOD which also destroyed the RGCs and optic nerve (563). These experiments confirmed that the RGCs and associated optic nerve fibers are sensitive to reduced complex I function and increased mitochondrial oxidative stress. They then showed that transduction of MnSOD cDNA into the retinas of NUDFA1 ribozyme treated mice protected the RGCs and the optic nerve (1424). Next, the Guy group prepared allotopic construct for the mtDNA ND4 gene with the normal sequence 11778G (340R) fused to the ATP synthase “c” polypeptide MTS and flag tagged. The mRNA was linked through an IRES GFP and inserted into the AAV pTR-UF11 transcribed from CMV enhancer–chicken  $\beta$ -actin promoter construct. This construct complemented the mitochondrial defects in 11778A (340H) mtDNA-containing cybrids (1425). MnSOD transduction also improved mitochondrial function of 11778A cybrids (1426). They then created an allotopic ND4 11778A (340H) construct and used AAV to transduce the RGCs resulting in disruption of the mitochondrial structure, increased ROS production, swelling of the optic nerve head, and increased apoptosis. The wild-type ND4 gene did not cause retinal pathology (1427). While concern has been expressed about inappropriate import of allotopic mitochondrial proteins (1419,1428), Guy’s group was able to demonstrate that the ND4 polypeptide entered the mitochondrial matrix and was incorporated into complex I (1429). They have further increased AAV transduction efficiency by using self-complementary AAV (scAAV) introduced into both mice and non-human primates (1430,1431).

Dr Corral-Debrinski and associates discovered a 3′-UTR that causes the allotopic gene mRNA to be translated on mitochondrially bound polysomes thus increasing the import of long-hydrophobic proteins into the mitochondrion (1421,1422). Large, hydrophobic proteins such as COX10 use this system to be imported into the mitochondrion through the TOMM and TIMM complexes concurrent with their translation. For the allotopic expression on the mtDNA-encoded proteins, they use the

COX10 MTS (21 amino acids) and 3'-UTR (1425 nt) to bracket the mitochondrial cDNA transcribed from the CMV enhancer-promoter (1421,1432,1433). With this and related constructs they have used allotopic ATP6 and ND4 genes to complement the mitochondrial defects of NARP ATP6 T8993G and LHON ND4 G11778A mutations in cultured cells (1434) and allotopic ND1 to complement the LHON ND1 3460A mutation (1435). They have also used allotopic gene plasmid electroporation of the RGCs to introduce the 11778A mutant ND4 gene into rat retinas and have produced a 30–38% reduction in the rat RGCs which were partially ameliorated when they also electroporated the allotopic wild-type ND4 11778G gene (1436). Finally, they have prepared an AAV2 vector harboring the apoptosis inducing factor (AIF) cDNA with its MTS and mitochondrial 3'-UTR and used intravitreal injection of this vector to complement the AIF genetic defect and associated complex I defect and retinal degeneration of the Harlequin mutant mouse (1437).

#### 11.6.2.2 Germline Mitochondrial Gene Therapy.

While somatic mtDNA gene therapy may hold promise for treating the symptoms of patients with mtDNA disease, these approaches will not help the woman who harbors a pathogenic mtDNA mutation, and would like to have children that are free of disease. Because maternal inheritance is absolute, all of her children will inherit her mtDNA and thus be at risk for the disease. To assure the future mother that her children will have normal health, it is necessary to break the maternal transmission of the mutant mtDNA. One procedure proposed in the 1980s that could accomplish this is nuclear transplantation. In this scenario, the nucleus of the mother's egg is removed by micropipette and injected into an enucleated oocyte from a woman with normal mtDNA. Subsequent fertilization of the modified oocyte with the father's sperm should result in mtDNA mutant-free offspring (331).

This has now been achieved in primates by the nuclear transplantation of the spindle of one *Macaca* oocyte into another oocyte. Subsequent fertilization and development has resulted in the normal development and the birth of normal offspring with less than 3% of the mtDNA carried over from the original oocyte (1438). This advance is now moving toward the clinic. Scientists in Newcastle, England have reported successful transfer of pronuclei between abnormally fertilized human zygotes in vitro with minimal carryover of donor mtDNA (1439).

## 11.7 A MITOCHONDRIAL PARADIGM FOR COMPLEX DISEASE

The pursuit of diseases resulting from mitochondrial gene mutations has revealed that energy deficiency can result in every symptom that has been attributed to the common metabolic and degenerative diseases. From a Mendelian genetic perspective, these common clinical problems appear to be “complex” in that they do not conform to standard chromosomal inheritance patterns. Hence, they have been assumed to be the results of the interaction of multiple

chromosomal loci plus the environment. However, there is another possibility and that is that the common metabolic and generative diseases are the results of systemic partial energy deficiencies and that the complexity in the genetics results from the assembly of the bioenergetic systems of the cell between 1000 and 2000 nDNA-encoded genes, the thousands of copies of the mtDNA genes, and the energetic regulation of the expression of the genes through the epigenome and the signal transduction systems.

Once we reorient our thinking about disease from the anatomical perspective of the current clinical subspecialties (neurology, ophthalmology, nephrology, etc.) to an energetic perspective, clinical problems that had been assumed to be separate entities suddenly become manifestations of the same pathophysiological mechanism, bioenergetic decline. Thus, as in the progressive failure of the electrical systems during a metropolitan brown out, as the energy production of the body declines the tissues with the highest energy demand will be the first to be affected.

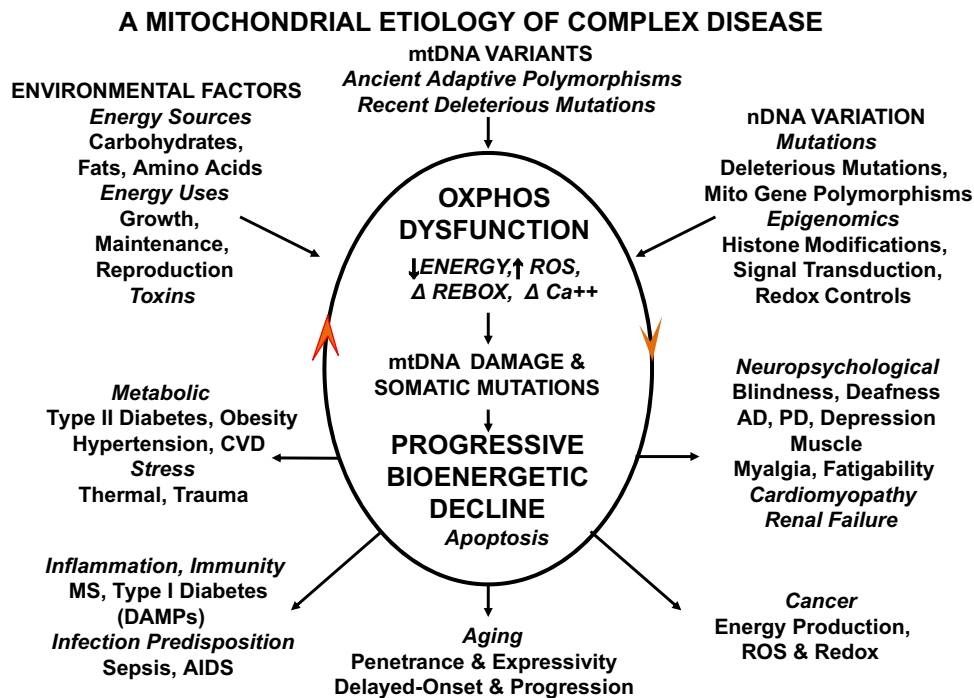

The assembly and regulation of the systemic energy system then provides the nexus for understanding the genetics and pathophysiology of the “complex” diseases. The central element for health and disease becomes mitochondrial energy production via OXPHOS. The capacity of OXPHOS to generate energy can be compromised in multiple ways. Alterations in the hundreds to thousands of nDNA genes involved in assembly and regulation of mitochondrial OXPHOS can occur through inherited mutations and/or polymorphic variants. The expression of the nDNA bioenergetic genes can also be altered by changes in the epigenome and the cellular signal transduction systems. OXPHOS can also be altered by either recent deleterious mtDNA mutations or ancient adaptive polymorphisms. Finally, mitochondrial OXPHOS is fueled by the availability of calories in the environment and impinged on by the demands made on energy flow for growth, maintenance, and reproduction. OXPHOS is also the most sensitive system in the body to effects of environmental toxins including pesticides and herbicides.

When mitochondrial OXPHOS is inhibited, this reduces energy production, alters the cellular redox state, alters  $\text{Ca}^{++}$  homeostasis, and increases ROS production. These impinge on mtDNA replication, repair, and turnover and result in the progressive accumulation of somatic mtDNA mutations. As the mutations accumulate, they erode mitochondrial energetic further, causing an age-related decline in mitochondrial function thus generating the aging-clock. When mitochondrial energy production becomes sufficiently impaired, the mtPTP can be activated and the energy impaired cell removed by apoptosis. The progressive loss of cellular function and ultimate loss of cellularity due to apoptosis results in organ and tissue functional decline which we call aging. This progressive stochastic energetic decline exacerbates inherited energetic defects until one or more tissues fall below the minimum energy output for them to function and symptoms ensue. This explains the delayed-onset and progressive course of metabolic and degenerative disease,

and the statistical variability seen in all complex diseases is referred to as their variable penetrance and expressivity.

The organs that are most prone to dysfunction resulting from partial energy deficiency are the central nervous system, cardiovascular system, skeletal muscles, renal, and endocrine systems. Hence, partial energy defects cause the most severe symptoms in these organs and result in forms of blindness and deafness as well as the clinical manifestations that we call LS, AD, PD, cardiomyopathy, renal failure, and so on. Moreover, since the mitochondria lie at the interface between the consumption of calories and the use of the energy generated, alterations in mitochondrial function are central to metabolic diseases such as diabetes, obesity, hypertension, and cardiovascular disease. The mitochondria are also the most prevalent bacteria in our bodies, with  $\sim 10^{17}$  bacteria in our cells but only  $10^{14}$  bacteria in our guts. The mitochondrial bacteria have naked DNA and N-formyl-methionine containing

peptides which are highly antigenic (572). Hence, apoptosis which is initiated by mitochondrial energy failure, excessive mitochondrial ROS damage, or  $\text{Ca}^{++}$  results in the destruction of the intracellular mitochondria before they enter the blood stream and can activate the innate immune system. However, apoptosis requires energy and severe mitochondrial energy failure leads to necrosis and the release of the mitochondria into the intracellular space and circulation. This then initiates the inflammatory response which can initiate the autoimmunity response. Hence, mitochondrial dysfunction may be an important primer of the immune response that leads to autoimmune diseases such as type 1 diabetes, multiple sclerosis, lupus, and so on. Finally, cancer cells are growing at a high rate and hence are continuously limited for both energy and substrates for cellular biogenesis. Hence, alterations in mitochondrial energy are central to neoplastic transformation and cancer cell growth as well (Figure 11–12).

**FIGURE 11-12** Mitochondrial etiology of “complex” diseases. An integrated model for the genetics and pathophysiology of complex diseases, aging, and cancer. The top of the figure indicates the three types of variations that impact on individual mitochondrial OXPHOS robustness and hence risk for developing disease symptoms. These include nuclear DNA (nDNA) variation encompassing DNA sequence changes and epigenomic modification of gene regulation and signal transduction pathways; mitochondrial DNA (mtDNA) variation including recent deleterious mutations and ancient adaptive polymorphisms, and environmental influences encompassing the availability and demand for calories and inhibition of mitochondrial function by environmental insults. The central oval encompasses the pathophysiological basis of disease processes and the basis of disease progression. The primary defect is reduction in the energy transformation capacity of OXPHOS. This can result in reduced energy output, increased reactive oxygen species (ROS) production, alter redox status, and altered calcium homeostasis. The decline in OXPHOS efficiency can in turn perturb mitochondrial biogenesis, increase ROS production, impair mitophagy, and so on resulting in the progressive increase in mtDNA damage and somatic mutations and further decline in mitochondrial function. Once mitochondrial function falls below the bioenergetic threshold of a tissue symptoms ensue. Continued energetic failure can initiate cell destruction by apoptosis or necrosis. The lower five derived disease categories summarize the phenotypic outcomes of perturbed mitochondrial energy transformation. The bottom arrow shows the effect of the stochastic accumulation of somatic mtDNA mutations resulting in delay-onset and progressive course of diseases and aging. The right arrow indicates clinical problems that can result from reduced energy production in the most energetic tissues, the brain, heart, muscle, and kidney. The number and severity of symptoms in these organs reflect the degree and specific nature of the mitochondrial defect. The arrow to the left indicates the metabolic effects of mitochondrial dysfunction which result in the perturbation of the body’s energy balance. This results in the symptoms of the metabolic syndrome. The arrow toward the lower right corner indicates the mitochondrial alterations that are critical for cancer initiation, promotion, and metastasis. The arrow to the lower right corner outlines the hypothesized inflammatory and autoimmune responses that may result from the chronic introduced into the blood stream of the mitochondria’s bacteria-like DNA and N-formyl methionine proteins.

## Biographies

**Doug Wallace, PhD** has been working on human and mammalian mitochondrial genetics for 40 years. He was the first to demonstrate that mammalian cells harbored cytoplasmically inherited genes by inventing the cybrid transfer technique in the early 1970s and used this system to demonstrate that mammalian chloramphenicol resistance could be transferred from cell to cell by fusing cytoplasmic fragments in the absence of a nucleus. He then proceeded to define the rules of mammalian mitochondrial genetics, culminating in his demonstration of the maternal inheritance of the human mitochondrial DNA (mtDNA) in 1980. His research then followed two paths: the investigation of the nature and extent of human mtDNA variation in aboriginal populations and the quest for diseases resulting from mutations in the mtDNA. The population studies revealed that mtDNA variation was unique in that it correlated highly with the ethnic and geographic origins of indigenous peoples. The quest for mtDNA diseases culminated with his 1988 report that Leber hereditary optic neuropathy was caused by an mtDNA missense mutation, making it the first maternally inherited mtDNA disease to be identified. Since that time, Wallace has shown that mtDNA variation is central to both rare and common multisystem diseases and aging.

**Vincent Procaccio, MD, PhD**, is Professor of Medical Genetics in the Department of Genetics and Biochemistry at the School of Medicine, University of Angers, France. He obtained his MD from Grenoble School of Medicine, his PhD from Grenoble University (France), and he is Board Certified Clinical Molecular Geneticist. From 2000 to 2003, he was a Post-Doctoral Fellow and worked on mitochondrial research at Emory University (Atlanta, USA). From 2003 to 2007 he was Assistant Professor and promoted Associate Professor in 2007 at the Department of Pediatrics, Center for Molecular and Mitochondrial Medicine and Genetics, University of California Irvine. Since 2008, he has been Professor of Medical Genetics and runs the Diagnostic Molecular Laboratory of Angers hospital, focused on genetic testing for mitochondrial and other genetic disorders. His research interests center on investigating the role of mitochondria in neurodegenerative diseases and mitochondrial disorders, with special emphasis on pharmacological and therapeutic aspects such as mechanisms of regulation of mitochondria by hormones.

**Marie Lott, MA**, is a bioinformatics specialist at the Children's Hospital of Philadelphia. She has 30 years of experience studying human mitochondrial DNA variation and disease with the Wallace group. She was part of the pioneering team that discovered the first LHON mutation at 11778, the MERRF mutation at 8344, and the "common deletion" in Kearns Sayre Syndrome. She is co-founder of the mitochondrial database Mitomap. She has been curator of Mitomap since its inception in 1995 with the goal of making available all information about the human mtDNA including its sequence, encoded functions, population variation, and clinical mutations.

# CHAPTER 12

## Multifactorial Inheritance and Complex Diseases

### 12.1 INTRODUCTION

If a disease or condition is caused by a single locus of large effect, it is called a single-gene or *monogenic* disease, disorder, or more generically, condition. There are over 10,000 such examples, which include cystic fibrosis, Huntington disease, Duchenne muscular dystrophy, and Marfan syndrome. It is possible that a single-gene disease has *locus heterogeneity* if that disease is caused by single mutations in different genes, but this is more properly considered a special case of an oligogenic disorder. For example, osteogenesis imperfecta is caused by single mutation in genes on either chromosome 7 or chromosome 17. *Oligogenic* disorders are explained by a few loci with large effects (for examples, see Reference (1)). In contrast to oligogenic traits, *polygenic* inheritance is due to many loci with small effects at each locus. Thus, the term *polygenic* is generally used to describe multiple factors that are exclusively genetic. Any of these genetic effects, with or without the combination of an environmental effect, can give rise to a *multifactorial* disorder. Multifactorial diseases are caused by the simultaneous action of multiple genetic and/or environmental factors.

In contrast to dichotomous traits (i.e. affected versus unaffected), quantitative traits are measured on a continuous scale, most of which are thought to be multifactorial (e.g. blood pressure and body mass index). Some quantitative traits may be due to major gene effects with a multifactorial background. Multifactorial inheritance is responsible for the majority of modern deleterious health conditions such as heart disease and diabetes. Atopic syndrome, diabetes, cancer, spina bifida/anencephaly, pyloric stenosis, cleft palate, congenital hip dysplasia, club foot, and many other disorders and complex phenotypes result from multifactorial inheritance.

### 12.2 DEFINITIONS AND TERMINOLOGY

The *polygenic model* has its origins from Fisher's seminal work (2), which showed that “many small, equal and additive loci” would result in a Gaussian (or normal) distribution for a phenotype. Similarly, the combined additive effects of many genetic and environmental factors will also produce an approximately Gaussian phenotypic distribution. To illustrate, suppose (naïvely) that a quantitative trait such as percent body fat is determined by a single gene with two codominant<sup>1</sup> alleles, *A* and *a*, which have equal frequency ( $p=0.50$ ). Assume individuals with an *A* allele tend to have a higher value of the trait, and individuals with an *a* allele tend to have a lower value of the trait. If *A* has an additive effect, then there are three distinct phenotypic groups, namely, high (2), intermediate (1), and low (0). If the allele frequencies of *A* and *a* are both 0.50, then 25% of individuals would be expected to be *aa* and of low-percent fat, 50% would be expected to be *Aa* and of moderate-percent fat, and 25% would be expected to be *AA* and of high-percent fat. Figure 12-1 gives the distribution of the trait in a population.

Now, suppose that the trait is determined by two loci. The second locus also has two codominant alleles, *B* for high and *b* for low expression of the trait, with *B* having an allele frequency of 0.50 and the same effect magnitude as the *A* allele. There are now nine possible genotypes (see Table 12-1).

<sup>1</sup>“An allele *a* is said to be codominant with respect to the wild-type allele *A* if the *A/a* heterozygote fully expresses both the phenotypes associated with the *a/a* and *A/A* homozygotes.”—from <http://www.informatics.jax.org/javawi2/servlet/WIFetch?page=glossaryTerm&key=codominant>.

**FIGURE 12-1** Expected phenotype distribution for a trait with a single causal locus with an allele frequency of 50% and in Hardy-Weinberg equilibrium.

TABLE 12-1 Frequency Distribution of Genotypic Values for Two Loci with No Linkage Disequilibrium			
	AA	Aa	aa
BB	0.0625	0.1250	0.1250
Bb	0.1250	0.2500	0.1250
bB	0.0625	0.1250	0.0625

An individual can possess 0, 1, 2, 3, or 4 “high”-trait alleles. Assuming that the combined effects of the two loci are also additive,<sup>2</sup> there are five distinct phenotypes with respect to the number of high-trait alleles (see Table 12-2).

The trait distribution with respect to genotypic value distribution is shown in Figure 12-2. As can be seen in Figure 12-2, even with two loci, the distribution of the phenotype starts to look Gaussian. An example of a three-locus system with equal allele frequencies, no linkage disequilibrium,<sup>3</sup> and equal additive effects, is shown in Figure 12-3. It can be shown that six diallelic loci are enough to produce population frequencies virtually indistinguishable from a normal curve.

Many traits (or diseases) are treated as dichotomous variables because they appear to be either present or absent (e.g. cancer). By definition, dichotomous variables do not approximate a Gaussian distribution. However, these diseases may still be polygenic or multifactorial because

TABLE 12-2 Genotypic Values of Two Loci Genotypes			
	AA	Aa	aa
BB	4	3	2
Bb	3	2	1
bb	2	1	0

**FIGURE 12-2** Expected phenotype distribution for a trait with two independently segregating causal loci of equal effect and allele frequency.

**FIGURE 12-3** Expected phenotype distribution for a trait with three independently segregating causal loci of equal effect and allele frequency.

they do not follow the patterns expected of Mendelian (single-gene) diseases. A common explanation is that an underlying *liability* distribution exists for multifactorial diseases (3). Individuals on the low end of the distribution have little chance of developing the disease because they possess few of the alleles or environmental factors that jointly cause the disease. By contrast, individuals on the high end of the liability distribution have a greater chance

<sup>2</sup>That is, not epistatic, where *epistatic* refers to an interaction (in the statistical, not necessarily biochemical sense) between two different loci, such that the effect of genotype at one locus depends on the genotype at another locus.

<sup>3</sup>*Linkage disequilibrium* is defined as the nonrandom association between alleles at *linked* (or adjacent) loci (133). Two loci are said to be *linked* if they are close sufficiently close on the same chromosome such that they do not segregate independently.

of developing the disease because they possess many of the alleles and/or environmental factors that jointly cause the disease. The liability distribution is assumed to be continuous (representing the sum of a large number of independent genetic and environmental factors) and normally distributed within the population. It is also a commonplace to assume that all correlations between relatives are due to shared genes but not shared environment. For multifactorial diseases that are either present or absent, there is a hypothesized *threshold of liability* that must be crossed before the disease is manifest (3).

For example, consider the development of the cleft palate. Early in embryonic development, the palatal arches are in a vertical position. Through embryonic and fetal development, the head grows larger, making the arches farther apart, and the tongue increases in size, making it more difficult to move. In addition, the arches themselves are growing and turning horizontally. There is a critical stage in development by which the two arches must meet and fuse. Head growth, tongue growth, and palatal arch growth are all subject to many genetic and environmental factors. If the two arches start to grow in time, grow at the proper rate, and begin to move soon enough to the horizontal, they will meet and fuse in spite of head size and tongue growth. The result is no cleft palate. They may fuse well ahead of the critical developmental stage or just barely make it in time; it is impossible to know. However, if they don't meet at the critical stage, a cleft palate results. If they are close together at the critical stage, a small cleft will result, perhaps only a bifurcated uvula. If they are far apart, a more severe cleft will result. That critical difference in liability is called the *threshold*. Beyond the threshold, disease results. Below the threshold, normal development is observed. Thus the underlying liability is distributed as the normal curve shown in Figure 12-4.

Some diseases may have more than one threshold, and commonly two liability thresholds are present as defined by factors such as gender, race, age of onset, and so on, causing different levels of severity (4). Examples include pyloric stenosis (sex dimorphism for liability) (5) and orofacial cleft syndrome/cleft lip and palate (two thresholds for fetal mortality and disease) (6,7). The latter model proposes a lower threshold level of liability resulting in a cleft formation and a higher level causing a fetal death (preferentially in males).

It should be emphasized that, similar to any other loci, the individual loci underlying a polygenic or multifactorial trait are generally assumed to follow the Mendelian principles of random segregation and independent assortment.<sup>4</sup> The difference is that they act together to influence the trait. Thus, the multifactorial model assumes:

**FIGURE 12-4** Liability distribution for a multifactorial disease. To be affected with the disease, an individual must exceed the threshold.

1. several, but not an unlimited number, of loci are involved in the expression of the trait;
2. the loci act in concert in an additive manner, each adding or subtracting a small amount from the phenotype; and
3. the environment interacts with the genotype to produce the final phenotype.

## 12.3 DETERMINING THE GENETIC COMPONENT OF A TRAIT

Historically, the genetic study of any trait can be divided into four broad categories: familial aggregation, segregation analysis, linkage analysis, and association studies. This paradigm was useful in discovering genes for many monogenic disorders.

### 12.3.1 Familial Aggregation

The first step of any genetic analysis is to establish a genetic component to the disease. In addition, one must establish the relative size of the genetic effect in comparison to other sources of variation, such as common household effect and random environmental effect.

*Familial aggregation* can be established using family-based or twin/adoption studies. Family members share genes and environment; therefore, familial aggregation of the trait could be due to genetic and environment together. In general, very few traits are influenced only by genes or only by the environment. Detection and estimation of familial aggregation is the first step in the genetic analysis of any multifactorial trait. Twin and adoption studies are traditionally used to determine the genetic component of the trait (8–11). As monozygotic

<sup>4</sup>Good descriptions of these principles can be found in the following web pages: <http://biology.about.com/library/weekly/aa110603a.htm> and <http://biology.about.com/library/weekly/aa100903a.htm>.

**TABLE 12-3** Using Twin Concordance and Discordance Rates to Test for a Genetic Component of a Disease

Twins	Concordant Pair	Discordant Pair	Total Pairs
MZ	$n_{11}$	$n_{12}$	$n_{MZ}$
DZ	$n_{21}$	$n_{22}$	$n_{DZ}$
	$n_C$	$n_D$	$n$

$$\chi^2_1 = \frac{n(n_{11}n_{22} - n_{12}n_{21})^2}{n_C n_D n_{MZ} n_{DZ}}$$

(MZ) twins share all their nuclear genes, any difference between them regarding a particular trait should be due solely to environmental effects. If the trait is completely influenced by genes, then MZ twins should have essentially identical expression of the trait. This is not true for dizygotic (DZ) twins because, on average, they share only 50% of their genes.
